## *Agradecimientos*

*A mis directores de Tesis, Agus y Lola, que son el motor principal de este trabajo. Gracias por contagiarme de vuestra pasión e impulsarme a llegar más lejos de lo que nunca imaginé. Gracias por todo, porque me habéis hecho sentir mil veces afortunada.*

*A mis compañeros y amigos del doctorado, que han sido de lo bueno, lo mejor de estos años. Gracias por haber compartido conmigo esta bonita etapa.  
En especial, a Esther y al petit comité, menciones más que merecidas.*

*Agradecer a mi grupo de investigación, MCMA y al Departamento de Química Inorgánica, por todos los recursos facilitados y la ayuda brindada.  
A Germán, por su inestimable contribución a esta Tesis.*

*To Prof. Andrzej Kotarba and his group from the Jagiellonian University. Kraków is always in my memories.*

*To Prof. Max García and his group from the Trinity College Dublin. See you very soon, my friends.*

*To the Langan family, who made me fall in love with Ireland.*

*A todas las buenas personas de las que he tenido la suerte de rodearme: los que siempre han estado, los que llegaron después, y los que ya no están. Por todo el apoyo y por cada lección, gracias.*

*A mi familia, mi pilar fundamental, porque este trabajo es también vuestro.*

# Summary of contents and Thesis structure

Universitat d'Alacant  
Universidad de Alicante

This Thesis is divided into 10 Chapters, and main description of each is presented in the following lines:

**Chapter 1** provides an extensive contextualization into the current opportunities for hydrogen utilization as energy vector, which is eventually dependent on an efficient CO clean-up processing step. In this regard, catalytic Preferential Oxidation of CO (CO-PROX) reaction, topic of this Project Thesis, is the most promising approach with excellent opportunities in mobile H<sub>2</sub>-dependent devices. This Chapter describes in detail the state-of-the-art of CO-PROX catalysts employed so far, among which, copper-based catalysts possess a great potential. At the end of Chapter 1, main objectives addressed in this Project Thesis are presented.

**Chapter 2** describes the methodology and research approach developed in this Project Thesis, comprising experimental techniques complemented with punctual computational calculations based on Density Functional Theory (DFT). The fundamental principles of each technique, instrumentation, experimental set-ups and specific operation conditions are presented in this Chapter, which will be referred henceforward in all along the Thesis extension.

**Chapter 3** reviews main significative advances achieved so far into the CO-PROX reaction mechanism study over CuO/CeO<sub>2</sub> catalysts, tested and fully characterized through a battery of techniques: N<sub>2</sub> physisorption at -196°C, X-Ray Diffraction (XRD), Temperature Programmed Reduction (TPR) and Raman spectroscopy, proving inherent synergistic Cu-Ce effects, which turn beneficial into the ongoing Mars-van Krevelen mechanism as demonstrated by pulse O<sub>2</sub>-isotopic exchange and *in-situ* Raman spectroscopy. Additionally, cutting-edge experimental techniques for the detailed molecular mechanism elucidation are presented herein. Namely, CO-PROX *operando* Near-Ambient Pressure X-ray Photoelectron spectroscopy (NAP-XPS), and X-ray Absorption Near-Edge Structure (XANES) experiments, reveal altogether clear evidences of CeO<sub>2</sub> very surface reduction, assigned to the role of CeO<sub>2</sub> in oxygen assistance to Cu<sub>x</sub>O in Cu – Ce interfacial points, when highly reduced Cu<sub>x</sub>O particles are inefficiently undertaking direct O<sub>2</sub> uptake at advanced CO-PROX reaction degrees. Finally, complementary DFT calculations confirm that lattice oxygen restitution by O<sub>2</sub> gas phase should be at first directly favored in Cu<sub>x</sub>O when partially oxidized, but then via CeO<sub>2</sub> when Cu<sub>x</sub>O particles are reduced at surface by the effect of the reaction course. Since reoxidation issues in CO-PROX reaction have been rarely addressed, this Chapter presents relevant insights for the state-of-the-art in the CuO/CeO<sub>2</sub> catalysts study.

**Chapter 4** presents a thorough Diffuse Reflectance Infra-red Fourier Transformed (DRIFT) spectroscopic study on CO-PROX reaction with model

---

CuO/Ce<sub>0.8</sub>X<sub>0.2</sub>O<sub>8</sub> catalysts (with X =Ce, Zr, La, Pr, or Nd). These have been fully characterized exhibiting different chemical features that correlate with catalytic activity. The CO oxidation rate over CuO/CeO<sub>2</sub> catalysts correlates with the formation of the Cu<sup>+</sup>-CO carbonyl above a critical temperature (90 °C for the experimental conditions in this study) because copper-carbonyl formation is the rate-limiting step. Above this temperature, CO oxidation capacity depends on the redox properties of the catalyst. However, decomposition of adsorbed intermediates is the slowest step below this threshold temperature. The hydroxyl groups on the catalyst surface play a key role in determining the nature of the carbon-based intermediates formed upon CO chemisorption and oxidation. Hydroxyls favor the formation of bicarbonates with respect to carbonates, and catalysts forming more bicarbonates produce faster CO oxidation rates than those which favour carbonates.

These results have been published in: Role of hydroxyl groups in the preferential oxidation of CO over copper oxide-cerium oxide catalysts. A. Davó-Quiñonero, M. Navlani-García, D. Lozano-Castelló, A. Bueno-López, J. Anderson. *ACS Catalysis*, **6(3)** (2016) 1723-1731.

In **Chapter 5**, Non-RE metal-based, Cryptomelane and CuO/Cryptomelane catalysts have been tested in CO-PROX reaction, paying special attention to deactivation and regeneration issues. Cryptomelane was stable during CO-PROX reactions in ramp experiments until 200°C and in a long-term isothermal experiment, exhibiting after use no changes neither in crystallinity nor H<sub>2</sub> reducibility. On the contrary, CuO/Cryptomelane, though being much more active, deactivated in consecutive CO-PROX reaction cycles performed until 200°C, but the catalytic activity was partially restored reoxidising the catalyst at 200°C or 400°C, the latter temperature being more effective. After four cycles of reaction, stable behavior was achieved, and then CuO/Cryptomelane demonstrated higher catalytic activity than that of Cryptomelane, even after its deactivation along cycles. Such deactivation has been attributed to potential causes: cryptomelane structure collapse into the crystallization of new phases (hausmannite (Mn<sub>3</sub>O<sub>4</sub>) and/or hopcalite (CuMn<sub>2</sub>O<sub>4</sub>)); segregation of potassium and decrease of the copper cations reducibility, whereas possible changes in the porous texture of CuO/Cryptomelane was ruled out.

These results have been published in: CuO/Cryptomelane catalyst for preferential oxidation of CO in the presence of H<sub>2</sub>: deactivation and regeneration. A. Davó-Quiñonero, M. Navlani-García, D. Lozano-Castelló, A. Bueno-López. *Catalysis Science & Technology*, **6(14)** (2016) 5684-5691.

The catalytic activity of CuO/Cryptomelane in CO-PROX reaction has been studied in the absence and presence of H<sub>2</sub>O and CO<sub>2</sub> in **Chapter 6**, paying special attention to the catalyst stability and to changes on its

physical-chemical properties. For fresh CuO/cryptomelane catalyst, the presence of CO<sub>2</sub> and/or H<sub>2</sub>O in the CO-PROX feed partially inhibits CO oxidation due to chemisorption of H<sub>2</sub>O and CO<sub>2</sub> on the catalyst. H<sub>2</sub>O chemisorption on CuO/Cryptomelane is stronger than CO<sub>2</sub> chemisorption, and simultaneous CO<sub>2</sub> and H<sub>2</sub>O adsorption has a synergistic effect that enhances co-adsorption and significantly hinders CO oxidation. On the contrary, the presence of CO<sub>2</sub> + H<sub>2</sub>O in the CO-PROX reaction mixture has a positive effect in the CuO/Cryptomelane stability upon several consecutive reaction cycles in the 25-200°C range. XRD showed that chemisorbed CO<sub>2</sub> + H<sub>2</sub>O species partially prevent the catalyst deactivation due to cryptomelane reduction to hausmannite (Mn<sub>3</sub>O<sub>4</sub>) under the strongly reductive environment of the CO-PROX reaction, and H<sub>2</sub>-TPR and Raman spectroscopy characterization support that the cryptomelane structure is less damaged under CO-PROX conditions in the presence of CO<sub>2</sub> and H<sub>2</sub>O than in the absence of these species. Therefore, interestingly under CO<sub>2</sub> + H<sub>2</sub>O environment (realistic CO-PROX conditions) CuO/Cryptomelane catalyst performs an improved catalytic activity once stable behavior is reached.

These results have been published in: Unexpected stability of CuO/Cryptomelane under Preferential Oxidation of CO reaction conditions in the presence of CO<sub>2</sub> and H<sub>2</sub>O. A. Davó-Quñonero, D. Lozano-Castelló, A. Bueno-López. *Applied Catalysis B: Environmental* **217** (2017) 459-465.

In **Chapter 7**, CuO/Cryptomelane catalyst was subjected to a mechanistic study over CO-PROX reaction by means of indirect techniques by the preparation, advanced characterization and testing of catalysts with different Cu nominal contents. Their CO-PROX catalytic activity has been tested in CO-PROX reaction and evaluated according to Cu dispersion and synergistic interaction between copper and manganese-rich phases. This work entails the use of conventional characterization techniques such as XRD, Raman, XPS and Auger spectroscopies, as well as complementary basic DFT simulation. Additionally, it is reported for the first time, *in-situ* Work Function measurements over CO and O<sub>2</sub> interaction in CuO/Cryptomelane catalysts. Results reveal a strong influence in the electronic properties of CuO/Cryptomelane depending on CuO-cryptomelane interaction at the interface contact points, which stabilize Cu<sup>+</sup> states upon Cu<sup>+2</sup>/Cu<sup>+</sup> and Mn<sup>3+</sup>/Mn<sup>4+</sup> redox interplay. The optimal performance is achieved by the efficient participation of two active species: (1) interfacial Cu<sup>+</sup>–Mn pairs, as the active sites for CO oxidation; and (2) CuO bulky particles for the efficient O<sub>2</sub> refilling. Thus, these results bring the conclusion that clear analogies exist within the ongoing CO-PROX mechanism involving copper species in CuO/Cryptomelane and the well-reported CuO/CeO<sub>2</sub> catalysts.

**Chapter 8** compiles main remarks referring to CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalysts utilization in the Preferential CO Oxidation reaction and the most relevant outcomes achieved along the development of

---

this Project Thesis are presented altogether for their direct comparison. With fresh sample on the reactor, CuO/Cryptomelane shows better performance than CuO/CeO<sub>2</sub> on a first catalytic run, but latter CuO/Cryptomelane deactivation on successive reaction cycles flips their relative activities. Nevertheless, in CO<sub>2</sub>+H<sub>2</sub>O environment, the enhanced stability of CuO/Cryptomelane allows to reach a much more active state after the succession of catalytic runs, which sets closer the CuO/CeO<sub>2</sub> and CuO/Cryptomelane performances, up to the point that the latter shows big competitive potential.

**Chapter 9** presents the study on the scalability of powdered copper-based active phases in medium-sized monolithic catalysts with unconventional designs prepared by means of 3D-printing technology. An improved honeycomb-like monolith with asymmetrical channels, where the channels section decrease along the monolith, was fabricated using a template prepared by 3D printing. A reference honeycomb monolith was also prepared in the same way but with conventional straight channels. Cu/Ceria active phase was loaded on these supports, and Scanning Electron Microscopy (SEM), Raman spectroscopy and XRD showed that the supported active phase is similar on both monoliths. The supported catalysts were tested for CO oxidation in excess oxygen and for preferential CO oxidation in H<sub>2</sub>-rich mixtures (CO-PROX), and the catalyst with the improved support achieved higher conversions in both reactions. The supported catalyst with asymmetrical channels has two benefits with regard to the counterpart catalyst with conventional symmetrical channels: improves the reaction rate with regard to the conventional one because fits better to the equation rate, and favors the turbulent regime of gases with regard to the laminar flow that prevails in symmetrical channels.

These results have been published in: Improved asymmetrical honeycomb monolith catalyst prepared using a 3D printed template. A. Davó-Quíñero, D. Sorolla-Soriano, E. Bailón-García, D. Lozano-Castelló, A. Bueno-López. *Journal of Hazardous Materials* **368** (2019) 638–643.

Finally, **Chapter 10** summarizes the most relevant conclusions obtained in this thesis.

Since this thesis applies for the International Doctorate Mention, it has been written in English and a summary in Spanish is included at the end of the Thesis to fulfil the requirements of this mention.

# CHAPTER 1

## Introduction

Chapter 1 provides an extensive contextualization into the current opportunities for hydrogen utilization as energy vector, which is eventually dependent on an efficient CO clean-up processing step. In this regard, catalytic CO-PROX reaction, topic of this Project Thesis, is the most promising approach with excellent opportunities in mobile H<sub>2</sub>-dependent devices. This Chapter describes in detail the state-of-the art of CO-PROX catalysts employed so far, among which, copper-based catalysts possess a great potential. At the end of Chapter 1, main objectives addressed in this Project Thesis are presented.

Universitat d'Alicante  
Universidad de Alicante

## 1.1 General introduction

### 1.1.1 Environmental concerns: an overview

The human activity track record in the industrial and economic development starting in the 20<sup>th</sup> century has resulted in a worrying environmental situation that is patent nowadays with irrefutable evidences. Namely, global warming [1] and ocean acidification [2] caused by anthropogenic emissions of greenhouse gases (GHG), mainly CO<sub>2</sub> [3]; air-polluted cities by industrial processes and vehicle motion with harmful effects in public health [4–6]; or the serious deforestation and persistent destruction of ecosystems by the uncontrolled utilization of natural resources [7].

In turn, the society is in general expressing a major sensitivity for the dramatic environmental consequences of the inaction and there is a rising consciousness to resolve and mitigate in the short-term the severe impacts of the non-sustainable development conducted so far. The 21<sup>st</sup> century is a critical moment in which we are meant to face two highly interdependent energy-related challenges: the sustainable economic growth and global climate change, targets in which catalysis science and technology may play a key role.

### 1.1.2 Future prospects and mitigation actions

According to near-future forecast, the global energy demand is predicted to grow in an unstoppable trend, along with the world economic development, which exhibits increasing growth rate year after year [8,9]. Thus, new power sources with sustainable carbon-neutral balance are an urgent imperative to avoid further energy-related CO<sub>2</sub> emissions according to current energy policies scenario.

In this regard, the Sustainable Development Goals (SDGs) adopted by world leaders in the United Nations' *2030 Agenda for Sustainable Development* [8] promoted, among other targets, the establishment of environmental protection compromises in a cooperative international framework. Whereas complementarily, the Nationally Determined Contributions (NCDs) made for the *Paris Agreement* in 2015 [11] meant a landmark agreement aiming to bring all nations into a common on cause on behalf of temperature rise mitigation.

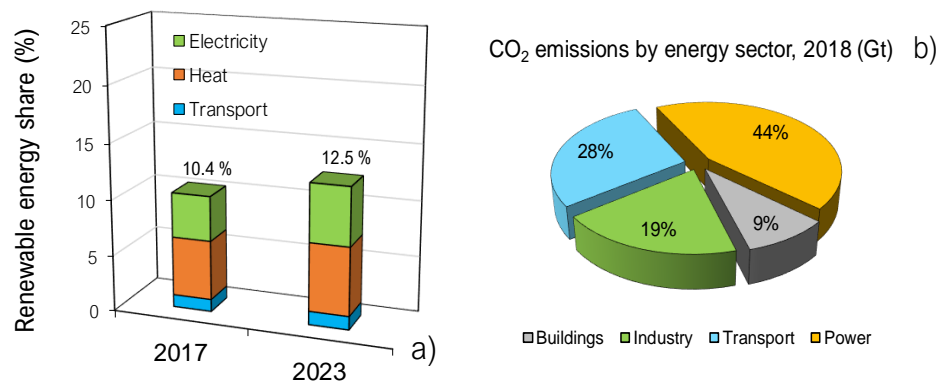

Nevertheless, despite efforts, 2018 recorded a historic of 33.1 Gt global GHG by energy-related CO<sub>2</sub> emissions, up 1.7% after 2015-2017 flat term [12]. Furthermore, according to future projections, these CO<sub>2</sub> emissions are alarmingly expected to continue increasing by 2030 and thereafter (Figure 1.1) [13].

**Figure 1.1.** Global energy-related CO<sub>2</sub> emissions, gigatonnes (Gt). Dashed lines describe forecasted trends in separate scenarios and colored areas the inferred relative contribution among different CO<sub>2</sub> mitigation strategies. Source: International Energy Agency, 2018 [12].

The reasons for the encountered recent setback against climate change was the large increase in primary energy demands accounted in 2018, which grew by nearly twice the average increment rate registered since 2010 [14]. Among global energy consumers, the strengthen emerging block from the non-OECD nations: Brazil, China, India and the Russian Federation, as well as the United States, experienced the largest growth [8] with mainly coal-powered economies, which had dramatical impact since coal is the largest single CO<sub>2</sub> emitter [12].

Hence, in order to meet long-term climate and other sustainability goals, it is imperative to accelerate in low-carbon and renewable energy development to increase their share in the global primary energy mix, which is expected to reach 12.4% by 2023. Among renewables, bioenergy currently holds 50% of total energy produced, followed by hydropower (31%), wind (9%), solar photovoltaic (PV) (4%), solar thermal (4%) and geothermal (2%) [15]. Furthermore, stronger energy efficiency policies are crucial, since these would allow to reduce energy consumption yet the increasing energy demands.

**Figure 1.2. a)** Share of modern renewable energy by sector in total final worldwide energy consumption, 2017-2023 [15]. **b)** Global energy-related global CO<sub>2</sub> emissions (Gt) by sector, 2018 [12].

Under current policies scenario, it is predicted that renewables will gain big importance in electricity sector, but their development is too slow and according to current pace, the share of renewables in the total energy share consumption will roughly reach 18% by 2040, much below a sustainable scenario benchmark [15]. In particular, renewable energy displays a very low base in transport sector, which is worrying indicator since large fraction of energy-related CO<sub>2</sub> emissions comes from aviation and transportation on road or rail modes (Figure 1.2), sectors considered hard-to-decarbonize.

### 1.1.3 Hydrogen as energy vector

In this scenario, big attention is attracted by the potential hydrogen (H<sub>2</sub>) deployment, thoroughly considered a key element with promising features to be used in the broad energy sector. Namely, hydrogen is a carbon-free fuel, with the highest energy content per unit mass (143.0 MJ/kg) [16,17] that releases no environmentally harmful compounds when burned neither contributes to CO<sub>2</sub> emissions, theoretically [18], in contrast with the fossil fuels.

However, the consolidation of a practicable and extended hydrogen market in the mid-term scenario exhibits certain challenges still pending to be resolved. Chiefly, despite being widely distributed as a component of water and other compounds, only traces of free hydrogen are present in the lower part of earth's atmosphere [19], so H<sub>2</sub> has to be produced by means of energy-consuming processes. In consequence, notice that H<sub>2</sub> is designated as an *energy carrier*, or energy vector, not as *energy source*, so that, the overall hydrogen economy sustainability is subjected to the energy cycle involved in production, too [20].

Likewise, storage and transport are additional vast drawbacks when it comes to hydrogen utilization, given the physicochemical properties of

gaseous  $H_2$ , like its lightness and high diffusion, volumetric energy density (the lowest, at 0.0108 MJ/L), and hazardous combination with air [20]. In this regard, a battery of well-reported options, such as high-pressure systems; cryogenic liquid hydrogen tanks; the formation of chemical hydrides; or adsorption in highly porous materials, show broad different gravimetric and volumetric hydrogen, but experimental systems capable to meet targets have not been found yet [16,17,21–23].

Conversely, despite the pending challenges involved,  $H_2$ -based technologies have already opened up entirely new approaches to integrate hydrogen in the energy system [24,25]. As a chemical fuel,  $H_2$  is a versatile *energy carrier* that can be traded and stored in ways that electricity cannot, enabling to tackle sectors with minimum disruption, as long-distance transport in hydrogen-powered vehicles and also power plants [15].

Namely, produced hydrogen can be stored over long periods and transformed to electricity when required (*power-to-power*) [26–28]; mixed into the natural gas network or converted to synthetic methane (*power-to-gas*) [29–31]; or directly introduced in hydrogen fuel cells (*power-to-fuel*) [32,33], electrochemical devices with vast potential in wide range of applications [34,35].

In particular, fuel cells (FCs) hold a very promising niche in transportation sector as implemented in Fuel Cell Electric Vehicles (FCEV). To date, FCEVs can provide the mobility service of today's conventional cars at potentially very low-carbon emissions [25,36]. As a positive indicator, the global FCEV car stock reached 8000 units in 2017 [37,38], though presenting very high manufacturing costs. However, it is encouragingly predicted that the cost of FCEVs will decrease up to 50% by 2030, being then closer competitor to conventional combustion vehicles [25], allowing a gradual decarbonization in road transportation sector.

Provided the large potential and promising outlook of FCs, these remain hot research topic since the last years, and main insights into fuel cell technology are presented in the following Section.

#### 1.1.4 Hydrogen Fuel Cells

##### 1.1.4.1 Basic principles

In fundamental terms, fuel cells (FCs) are electrochemical devices able to convert chemical energy into electrical energy by means of a direct and efficient process spurred by an applied potential difference. By and large, the basic operation of a fuel cell requires a combustible substance, such as  $H_2$ , and an oxidant, or comburent, as  $O_2$ , which are supplied separately to the electrode compartments, anode and cathode, respectively, where electrochemical processes are physically taking place. In order to accelerate

reactions up to a relevant rate, a suitable catalyst must be deployed in both electrodes, specially, in low-temperature operation fuel cells, provided the very slow intrinsic kinetics.

**Figure 1.3.** General scheme of a hydrogen fuel cell simple configuration.

As Figure 1.3 depicts, the electrodes are connected by an ionic-conducting solid or liquid electrolyte media, which is selectively permeable to specific ions; while electrically connected by current collectors to an external circuit that allows to produce electrical energy upon the generated current. Since fuel cells operation requires from a continuous supply of reactants, characteristic feature of the so-called *tertiary cells* [39], FCs may tentatively remind to a certain extent, to combustion machines, though much higher efficiencies can be achieved since FCs skip the intrinsic limitation of Carnot cycle [40,41].

Generally, multiple cells are connected together in stacked assemblies, so separator elements, the bipolar plates, are included in the design. These not only keep the electrical interconnection between the different cells, but also, their grooved design promotes the efficient gas inlet and products outlet paths. Moreover, edge sealing gaskets prevent from leaks, enabling the safe handling of gas and liquid components and an adequate fuel cell configuration should allow proper heat management to ensure safety and enhance durability [53,54].

#### 1.1.4.2 Fuel Cell types

Table 1.1. shows the main fuel cell categories and their diverse characteristics, which evidence the large versatility over FC technology. As common aspects, fuel cells present very positive features in terms of high efficiency, simplicity, silent operation and lack of noxious emissions. However, the prohibitive high expenses involved in fuel cell technology, and

their limited durability are currently very strong barriers on their extended implementation [42–44].

For most of the fuel cell types, the preferred fuel is hydrogen, though hydrocarbons and alcohols can be used, too. Regarding the gas inlet feeding requirements, whereas the choice of oxidant for the cathode is either air or oxygen, the selection of an appropriate fuel is not so straightforward, and notice that for some fuel cell types, it is emphasized that *pure* H<sub>2</sub> is the demanded anode feeding [54]. The degree of required purity is determined by the compatibility of the electrodes and electrolyte with certain impurities present in H<sub>2</sub> streams, which is highly dependent on the operation temperature. So that, in general terms, purity demand becomes more stringent with the lower temperature.

Likewise, as a very positive feature in the high-temperature fuel cell types, Molten-Carbonate Fuel Cells (MCFCs) and Solid Oxide Fuel Cells (SOFCs), hydrocarbons standalone can be directly fed to the cell, to be either electrochemically oxidized or *in-situ* converted to hydrogen by internal reforming and latter electrooxidation [32]. In turn, current natural gas pipelines and the available distribution infrastructure is as well valid for the high-temperature fuel cells feeding, enabling their operation where required, bypassing hydrogen production, transportation and storage issues [33]. Today, MCFCs and SOFCs are highly utilized in combined heat and power systems, provided their high-grade waste heat.

However, hydrogen-fuelled *Polymer Electrolyte Fuel Cells* (PEFCs), are preferred for automotive applications, since they present immediate start-up and offer much higher power densities than any other FC type.

In PEFC, the electrolyte is a solid polymer, which is an ionic-conducting membrane permeable to H<sup>+</sup> (proton) or OH<sup>-</sup> (hydroxide) ions. In turn, two different sub-categories are found: *Proton Exchange Membrane* (PEM); and *Anionic Exchange Membrane* (AEM) fuel cells; respectively [48]. In general terms, proton exchange membranes exhibit higher conductivity and reliability [49,50]. Besides, working with acid media turns into better catalytic performances, so the required catalyst loading is significantly lower in PEM, with regards to AEM devices [51,52]. As a result, because of practical interest, most of the commercial fuel cells and related research have focused mainly on PEM fuel cell configuration, which is revised in the next Section 1.2.

**Table 1.1.** Fuel cell types and main characteristics [34,39,41,45–48].

Fuel cell type	Electrode feeding; catalyst	Electrolyte; Mobile ion	Operation range (°C); Power range (W) <i>Start-up</i>	Field of application
<b>PEFC:</b> Polymer electrolyte fuel cell  (1) <b>PEM:</b> Proton Exchange Membrane  (2) <b>AEM:</b> Anionic Exchange Membrane	<u>Anode (-):</u> <b>Pure H<sub>2</sub></b> ; Pt/C catalyst  <u>Cathode (+):</u> <b>O<sub>2</sub>/air</b> ; Pt/C and alternatives	Ionic-conducting polymer membrane (1) <u>In PEMFC:</u> <b>H<sup>+</sup></b> (proton)  (2) <u>In AEMFC:</u> <b>OH<sup>-</sup></b> (hydroxide)	<b>30-90 °C;</b> 1-100 kW <i>Immediate</i>	Road vehicles, stationary electricity generation, heat and electricity co-generation, submarines, space travel  Most commercialized

<b>SOFC:</b> Solid-oxide fuel cell	<u>(-): Gasoline or natural gas</u> ; porous cermet of Ni or Co and yttria-zirconia <u>(+): O<sub>2</sub>/air</u> ; strontia-doped lanthanum-manganite perovskite	Ion-conducting ceramic (yttrium-stabilised zirconia); <b>O<sup>2-</sup></b> (oxide)	<b>~900 °C;</b> 1 kW-100 MW <i>Several hours after cold start</i>	Stationary electricity generation, heat and electricity co-generation Hydrocarbon fuels reformed in situ

## 1.2 Proton Exchange Membrane (PEM) fuel cells

### 1.2.1 PEM fuel cell operation

Briefly, PEM fuel cells operation is well-known and can be summarized as follows [34,41]: (1) In the anodic side, inlet  $H_2$  gas flows towards the catalytic layers where it is oxidized in the Hydrogen Oxidation Reaction (HOR) (Equation 1.1). (2) In the cathode, the oxidant inlet ( $O_2$  or air) is electro-reduced to  $H_2O$  by means of the Oxygen Reduction Reaction (ORR), which is ideally simplified as (Equation 1.2).

Notice that according to the global process,  $H_2O$  is released as the lone overall exhaust product. Likewise, a proper outlet product release strategy is critical, in order to guarantee the fuel cell durability. Namely, an adequate  $H_2O$  management is necessary to keep suitable humidity levels and maintain invariable the properties of the membrane and electrodes [45, 53]. Meanwhile in the anode, the  $H_2$  excess, should be reconducted in outlet lines and recirculated back towards the anode to gain fuel efficiency.

### 1.2.2 Challenges and fundamental research over PEM fuel cells

For the sake of extended implementation and commercialization, there are three main criteria that fuel cell technology must fulfill: cost, performance and durability, the targeted pillars on which fuel cell research is based [35,54,55]. Particularly, the rational optimization of the catalysts comprises all of them, since they directly influence the performance, limit durability and involve major costs derived from fuel cells [25,56]. In this regard, fundamental research has enabled remarkable advances, such as the design of high-performance membrane-electrode assemblies (MEAs) [39,54,57].

Figure 1.4 depicts a cross-section of a PEM fuel cell, exhibiting a typical MEA configuration [58,59].

**Figure 1.4.** PEM fuel cell electrode assembly and electrochemical processes involved.

Thus, PEM fuel cell electrodes are commonly constituted by three main elements. Namely, **(1)** the Gas Diffusion Layer (GDL), carbon fiber paper (Toray); together with **(2)** the Micro-Porous Layer (MPL), usually fabricated by intermixing a hydrophobic polytetrafluoroethylene with carbon black; provide the adequate multi-physics media and enable coupled mobility of electrons and gas diffusion, while facilitating water transport [60]. And last, **(3)** the Catalytic Layer (CL), where electrochemical processes anodic (HOR) and cathodic (ORR) take place. The most common CL configuration, and well-established reference catalyst, comprises very small Pt nanoparticles (2-5 nm) finely dispersed in carbon-black powder, *i.e.*, Vulcan-XC72® (Cabot) [57].

Since the electrochemical processes are confined to occur in the triple-phase boundaries (TPB), that is, the interface region between the protonic membrane and the Pt/C particles [61], most attempts to improve the catalytic activity are focused on the maximization of exposed area of the Pt/C catalyst to enable efficient contact with the electrolyte. For instance, the advanced preparation of high-surface catalytic thin films, so-called extended surface area catalysts [54,62], as well as novel Pt deposition procedures [63], are well-reported approaches that have allowed powerful enhancements in catalytic activity, while reducing by large Pt content.

Nevertheless, despite the thorough optimization over the years, the costs of PEM cell devices remain still prohibitive because of Pt utilization. Furthermore, the severe scarcity of Earth's Pt resources turns unfeasible the widespread implementation of PEM fuel cell devices with current demanded loading. Noticeably, the Pt content in PEM electrocatalysts has dramatically decreased, from 28  $\text{mg}\cdot\text{cm}^{-2}$  in the first commercial devices, to  $\sim 0.4 \text{ mg}\cdot\text{cm}^{-2}$ , yet increasing overall activity in current systems [57,64].

Thus, although present in both electrodes, the cathode side contains nearly the 90% of total Pt content in the cell [65], since the sluggish kinetics and mechanistically complex ORR process require far more Pt to deliver high currents, when compared to HOR. In fact, Pt-catalyzed HOR is extremely facile and exhibits kinetics  $10^5$  to  $10^7$  times faster than ORR [66], the reason why current platinum share in the PEM fuel cell is usually  $\sim 0.4 \text{ mg}\cdot\text{cm}^{-2}$  in the cathode and  $\sim 0.05 \text{ mg}\cdot\text{cm}^{-2}$  in the anode. Conversely, to result economically feasible, it has been targeted that total Pt content (anode + cathode) should not overcome the maximum  $0.125 \text{ mg}\cdot\text{cm}^{-2}$  loading in PEM fuel cells, [56], which is a vast research challenge [67].

In this scenario, great majority of studies focus on ORR rather than HOR, since ORR optimization is much more necessary and results determinant to achieve improvements in the overall fuel cell performance. Among the different strategies conducted so far, the most studied is Pt alloying, which dilutes Pt content with the presence of secondary metals that modify electronic properties of Pt, too [48,54,68–70]. Additionally, multiple non Pt-based alternative catalysts have been developed, such as Pd and its alloys [71], Rh, Ir [72]; non-noble metal catalysts such as metal-organic complexes [73], enzymes [74], oxides [75] or functionalized N-doped carbon materials [76,77]. Nevertheless, the use of non-Pt alternative active materials has presented important drawbacks as limited durability and poorer performance when compared to Pt/Vulcan reference catalyst, and even though some total Pt-free configurations have arisen [78–80], Pt and Pt-based alloys are still the catalyst choice by excellence for PEM fuel cells.

### 1.2.3 Pt-based electrodes susceptibility

Apart from the logistic issues related to Pt deployment, another relevant drawback facing the PEM fuel cell commercialization is the electrode susceptibility to potential impurities in  $\text{H}_2$  streams, such as carbon monoxide (CO), or sulfur compounds ( $\text{H}_2\text{S}$ , or COS).

For Pt-based catalysts, specially in acid media, CO leads to an activity loss and damages seriously the durability of the fuel cell, even when present in very low trace levels. This effect is attributed to the strong CO-Pt binding, which blocks preferentially and irreversibly Pt electrocatalyst active sites at the low-temperature operation of PEM fuel cell [81,82]. Specifically, adsorbed CO prevents the dissociative electro-sorption of molecular hydrogen in Pt sites, which is the rate-limiting step in HOR [83,84]. On the other hand, although CO-containing fuel is only fed to the anode side, physically separated from the cathode, it has been reported that CO could occasionally cross through the membrane reaching cathodic electrode and causing detrimental effect in ORR performance, too [85,86].

Recent standard requirements over H<sub>2</sub> streams composition for PEM FC applications with Pt/C catalysts set the maximum CO concentration at the very strict 0.2 ppm values (ISO 14687-2, SAE J2719) [87]. Nevertheless, conducted efforts into the design of CO-resistant catalysts have expanded the acceptable tolerance levels up to 10-100 ppm CO in certain configurations, yet depending on the fuel cell specifications [88–91].

Tentatively, a first approach to mitigate CO contamination could be to rise the temperature of operation, from conventional ~80°C to 100-200°C, since it is well-known that CO tolerance increases with temperature [92]. However, increasing the temperature decreases significantly the membrane lifetime and hampers to keep its suitable humidity. Hence, currently there is considerable interest on the development of high temperature performance membranes, but these have not demonstrated sufficient stability yet [93].

Provided that increasing the temperature seems to be impracticable for the moment, current attempts to suppress electrode CO contamination are centred on the preparation of bimetallic Pt-based anodic catalysts, such as Pt-Ru [88,89,94], Pt-Sn [95,96], Pt-Fe [90,97,98] or Pt-Mo [91,99]. The mitigation of the CO problem by Pt-alloying is ascribed to mainly two different effects, such as: the promotion of CO electrooxidation by OH species formed in the second metal sites, so-called *bifunctional effect*, or the modification of Pt electronic properties for the Pt-CO bond weakening, also known as *ligand effect*. Among the binary combinations, Pt-Ru/C catalysts have been most studied because of their well-known enhanced CO-resistance, as well as high performance [81,88,100]. In fact, further optimization of morphological aspects [88], or ternary combinations [101], core-shell architectures [102] or the incorporation of different metal oxides [103,104] have presented acceptable results towards gaining CO-tolerance, though stability of such configurations over long-time operation is still unclear [100].

Complementarily, several approaches have been proposed to palliate the CO contamination effects on PEM fuel cells, which mainly rely on the conversion of the poisoning CO, to the harmless CO<sub>2</sub>, by means of different set-ups. For instance, *air bleeding*, consists in the introduction of low contents (2-5%) of O<sub>2</sub> (from air) into the H<sub>2</sub> stream, so the Pt-catalyst itself activates CO oxidation reaction (Equation 1.3), process that removes sorbed CO, and, therefore, suppresses CO-poisoning [105–107]. Conversely, the addition of O<sub>2</sub>, a comburent, beside the combustible, H<sub>2</sub> in the presence of a catalyst, facilitates also the undesired direct H<sub>2</sub> oxidation reaction (Equation 1.4)

Nevertheless, apart from the efficiency loss by the fuel consumption, the main drawback over air bleeding technique is the local temperature increase within the MEA because of the very exothermic CO oxidation and H<sub>2</sub> oxidation reactions occurring in the anode layer, causing Pt sintering and consequent activity loss. In this regard, a possible modification of air bleeding procedure is the incorporation of an additional Pt-catalyst layer between the MPL and the Pt or Pt-Ru catalyst layer (CL), configuration named *bilayer anodes* [108]. In turn, the CO and H<sub>2</sub> oxidation reactions would take place in the intermediate layer, while temperature would remain controlled in the CL for stable HOR operation. Nonetheless, despite good operation, the complex bilayer anodic assembly presents additional costs to the fuel cell manufacturing, which is, precisely, not wanted. Yet, in-situ regeneration of CO-poisoned electrodes has also been reported by means electrical pulsed CO oxidation techniques [109–111], but, there is still much lack of understanding of the complicated potential oscillations in the PEM system, and despite good results, the set-up presents uncertain safety issues which hinders extended implementation.

In conclusion, despite conducted efforts, CO poisoning over well-consolidated Pt and Pt-alloyed electrocatalysts is still an unresolved challenge. Besides, considering other additional contaminants present as impurities in H<sub>2</sub> streams, such as H<sub>2</sub>S or SO<sub>2</sub>, which cause severe damage in the Pt-based catalyst, even more detrimental and more difficult to mitigate than with CO [82,112], the durability of PEM cell utilization becomes critical.

As a consequence, it is an urgent requirement to set a particular research focus into the efficient and exhaustive H<sub>2</sub> purification, to clean-up CO and sulfur species from stream to the *ppmv* tolerance levels, in order to ensure the prospective PEM fuel cells utilization.

### 1.3 Fuel processing for fuel cell applications

Provided that purity requirements over inlet hydrogen in PEM fuel cell is very stringent, several methodologies have arisen to produce clean H<sub>2</sub> streams aiming to tackle this particular application. Thus, the target utilization of PEM fuel cell, whether in large or small-scale, either portable or stationary application, will determine the most suitable strategy among the existing battery for pure hydrogen production technology.

In the case of automotive PEM fuel cells, these are generally fueled with gaseous hydrogen stored in high pressure tanks (35 to 70 MPa), seeking large hydrogen capacity within acceptable volume constraints in order to meet the sufficient vehicle autonomy. Such high pressure containers require of expensive composite materials that significantly increase overall costs [113] besides depend on extremely expensive refueling stations and a proper distribution network supplied by large-scale high-purity hydrogen production

plants [25], which in overall should accomplish demanding critical features [114].

Conversely, as an alternative fueling mode, the *on-board* fuel reforming concept rose to be implemented in low-temperature PEM fuel cells, in analogue approach to the *in-situ* hydrocarbon reforming process carried out in the high-temperature MCFCs and SOFCs [115,116]. Thus, *on-board* reforming would allow direct hydrocarbon supply to the automotive system, comprised mainly, by a fuel reforming reactor, for the hydrocarbon conversion to  $H_2$ ; and the coupled PEM fuel cell, among other elements as schematized in Figure 1.5.

**Figure 1.5.** *On-board* fuel reforming operational scheme.

The exploitation of *on-board* reforming concept was initiated in the 1970s [115,117,118] which came long way and relevant outcomes were achieved, as one of the first FCEVs prototype. However, a seismic shift occurred when in 2004, the US Department of Energy in 2004, determined to stop further research funding in the field at expenses of hydrogen storage technology investments [116,119], decision that brought ground to a halt *on-board* reforming achievements, comprising hydrogen production and purification at portable scale by means of an advanced catalysis science development.

Nevertheless, although the DOE support would had been a key driver, *on-board* research has been taking place in a second plane during last decade, and currently hold relevant niche in the recently developed *exhaust gas reforming* concept, for the sake of the partial hydrogen introduction in fuel mixture over conventional engines [120,121].

In agreement with this contextualization in PEM fuel cells application, next sub-sections review most relevant hydrogen production and purification pathways.

### 1.3.1 Current hydrogen market status

To date, hydrogen production accounts for ca. 7.7 exajoules (EJ) every year, mainly targeted to ammonia production and oil refining industries [122] in a growing global H<sub>2</sub> market forecasted to rise up to 10 EJ/year by 2050. Regrettably, most of hydrogen production relies on fossil fuels: coal, oil and natural gas, which paradoxically results in significative CO<sub>2</sub> emissions associated to H<sub>2</sub> utilization.

Figure 1.6. schematizes principal H<sub>2</sub> generation pathways with current available technologies, yet in different stages of development, large and small-scale. In terms of efficiency and volume of production, steam reforming of natural gas is by large, the preferred and most extended, accounting for nearly 48% of produced H<sub>2</sub>. Next, oil reforming and coal gasification contribute with the 30% and 18%, respectively, whereas merely the balance of total H<sub>2</sub> is produced by water electrolysis [25].

**Figure 1.6.** Principal H<sub>2</sub> generation routes by primary sources, and energy-related uses.

That is to say, only a mere 4% fraction of overall large-scale produced H<sub>2</sub> is not fossil fuel dependent, at least, not directly. So short-term research goals in the field are determined to optimize water electrolysis and increase its share in hydrogen production market.

### 1.3.2 Electrolytic water splitting

By and large, electrolysis is the process of splitting water (Equation 1.6) into its elemental compounds, H<sub>2</sub> and O<sub>2</sub>, by using electrical current applied between two electrodes in electrochemical devices, electrolyzers or electrolytic cells (EC) [123–125].

As a result, *pure* H<sub>2</sub> and O<sub>2</sub>, a useful by-product, are created in a very efficient process with virtually, zero carbon emissions involved. However, water electrolysis is obviously conditioned by the expenses of the required electricity and by the environmental impact related to its production. In this regard, taking into account current electricity production scenario, investments in water electrolysis technology are just not globally accountable in terms of cost, beside it results in large amount of indirect CO<sub>2</sub> emissions [126].

Technically, only renewable electricity production may drive to zero-emission electrolytic H<sub>2</sub>, which is the premise in current worldwide *power-to-x* plants [30], aimed to use renewable electricity surplus in off-peak times to produce electrolytic hydrogen. Stored as chemical energy, it can be delivered afterwards when demanded in the fluctuating renewable electricity generation. However, much efforts are pending in this regard as, to date, though implemented mature electrolytic technology, few pilot plants have demonstrated sufficient long-period operation and cost-efficiency.

### 1.3.3 Steam Reforming and Water-Gas Shift reaction pathway

Hence, in the transition to the sustainable H<sub>2</sub> economy alongside the gradual progress on water electrolysis technology deployment, the current H<sub>2</sub> market is mainly sustained by Natural Gas Steam Reforming (NGSR), an economically affordable process most often produced in large dedicated plants managed by industrial gas companies [25]. Although composed of a mixture of light hydrocarbons, natural gas is mostly methane (CH<sub>4</sub>), so an approximate description of NGSR is provided by Equation 1.7.

Noticeable, hydrogen generation via steam reforming comprises a significative CO co-production, leading to a H<sub>2</sub>-rich mixture with a variable 10-12% vol. CO, depending on the operation temperature and the inlet feed [127,128]. The outcome reducing mixture, so-called *synthesis gas* or shortly, *syn-gas*, is standalone a good fuel and a relevant intermediate in chemical industry such as in ammonia, or methanol production, and feedstock in Fischer-Tropsch process, among multiple uses [129,130]. Nevertheless, the variable syn-gas mixture is not suitable for stoichiometric applications and if pure hydrogen is demanded, the outlet reforming stream has to be treated in a subsequent refinement process, namely the Water-Gas Shift (WGS) reaction (Equation 1.8).

Consequently, the outlet stream is enriched in H<sub>2</sub> while CO content lowered to the variable 0.5-2% [127,128,131], yet insufficiently clean to be directly fed in the PEM fuel cell, according to the well-known stringent ppmv

CO-tolerance of Pt-based anodes. So latter purification processes are required to achieve targeted CO removal. Among different strategies to conduct CO clean-up, the catalytic methods allow much better miniaturization of the process since they do not need specific heavy components for their set up. In particular, as described in detail in the following sections, the Preferential CO Oxidation (CO-PROX) reaction has been claimed as the most promising approach [127,132], besides it brings the possibility to undertake the so-called *process intensification* concept, aiming to unify WGS and CO-PROX reactions in a single advanced catalytic reactor, which may reduce costs and overall system volume requirements [133].

**Figure 1.7.** Conventional unit operations for generating hydrogen from natural gas.

Thus, in the overall  $H_2$  production by coupled NGSR and WGS processes, engineering design is meant to overcome thermodynamic limitations and favor the corresponding forward reactions to the products side [134,135]. Furthermore, in order to accelerate reaction kinetics up to a relevant rate, catalysts with specific formulations are employed on each operational unit. Figure 1.7 schematizes principal chemical processes in a conventional  $H_2$  production plant, and in the following sub-sections the main characteristics of the catalytic processes are described in detail.

### 1.3.3.1 Sulfur removal

Provided that natural gas may come from different geological sources according to local availability, the reforming fuel feedstock presents variable composition, such as sulfur compounds from different nature (R-S). Since sulfur is a strong poisoning agent that permanently deactivates the subsequent Ni-based reforming catalyst, the exhaustive sulfur removal is a critical first step to guarantee overall reforming process and PEM fuel cell operation [136–138].

Typically, sulfur removal from natural gas takes place in two steps:

- (1) *Catalytic hydrodesulfurization*, that is, the retention of the sulfur-containing hydrocarbon (R-S) into solid catalysts and adsorbents (Co,

Mo/Alumina) at elevated temperatures (300–400 °C) and pressures (30–40 bar). When an equilibrium sulfur composition is achieved (catalyst sulfide formation), the excess sulfur is released as H<sub>2</sub>S [139], so the overall process can be described as in Equation 1.9:

(2) *Sulfur adsorption*, which comprises the H<sub>2</sub>S retention on particulate high-surface ZnO bed, occurring at 400°C, process that is actually controlled by the reaction defined as Equation 1.10, that forms inert insoluble zinc sulfide [140]:

The spent ZnO sorbent is non-hazardous for waste disposal, and by these coupled processes, sulfur levels can be successfully decreased up to 0.02 ppmv in the fuel stream [127].

#### 1.3.3.2. Steam Reforming reaction

After desulfurization, S-free fuel enters the steam reforming reactor. Since methane steam reforming reaction (Equation 1.7) is strongly endothermic, high temperatures are required to favor thermodynamics, so typically the reactor should operate above 700°C [134,135]. However, different strategies allow to lower operation temperature up to nearly 500°C [141]. For instance, the *in-situ* removal of either or both H<sub>2</sub> and CO<sub>2</sub> shifts equilibria towards product side, which can be performed by means of H<sub>2</sub>-selective membranes [142] and/or CO<sub>2</sub> solid sorbents [143], integrated in the conveniently designed reactor operating at high pressures (3-25 bar) [144]. On the other hand, modern steam-reforming units consist of a primary reformer with an adiabatic pre-reformer upstream, which reduces the load of the primary reformer, and minimizes the risk of sulfur poisoning [145].

Among active materials to accelerate methane steam reforming, two main categories are generally discerned: (1) catalysts based on precious metals, such as Pt or Rh; and (2) based on non-precious metals, as Ni, or Co [146,147]. By large, the most employed catalysts in industry are based on the less expensive nickel formulations, chiefly, Ni dispersed in the refractory support alumina (Al<sub>2</sub>O<sub>3</sub>). However, at high temperatures nickel-based catalysts may promote coke formation, leading to carbon deposition on the catalytic surface with corresponding active site blocking, specially when feeding low steam to carbon ratios into the reactor [148,149]. In this regard, structural and electronic promoters such as Mg, K or other alkaline components are added to the support to prevent from massive coke deposition [127,128,150,151].

In general, steam reforming is a mature industrial process with low initial investment costs, long life time and efficiencies reaching the 85%, for which it is well-established and covers most of hydrogen production [152,153]. Furthermore, despite environmental impact because of fossil fuels utilization, low carbon emissions via steam reforming industrial process is feasible if appropriate CCS strategies are implemented to the highly-concentrated CO<sub>2</sub> output streams, which are optimum targets for CCS technology [25]. In fact, almost 80% of CO<sub>2</sub> emissions can be reduced by coupling CCS, so reformat hydrogen could be tentatively considered a low-carbon fuel if CCS mitigation measures are installed. This remark is quite encouraging, since it is possible to provide certain sustainability to current hydrogen production market while enabling the interdependent fuel cell implementation and development.

#### 1.3.3.3 Water-Gas Shift

The effluent reformat gases are introduced into the WGS reactor and which typically operates at two catalytic stages, in order to achieve higher CO conversion. Firstly, in the high-temperature (HT) shift, operating near equilibrium in the 320-450°C range, lowers initial CO content to ~4%. Secondly, the low-temperature (LT) shift, performed at 180-240°C allows to decrease CO content up to targeted 0.5-2% CO vol. in the WGS output [139,154,155]. Because of thermodynamic limitations, WGS process cannot decrease farther CO content in the H<sub>2</sub> stream to meet PEM Pt-based electrodes requirement, but the choice of a proper catalyst for both HT and LT bed is critical for the well performance of the WGS unit.

In conventional design, catalysts for HT and LT processes employ well-known standard formulations. For the HT, it comprises the mixture: Fe<sub>2</sub>O<sub>3</sub> (80-90%) and Cr<sub>2</sub>O<sub>3</sub> (8-10%), balanced with promoters (Al<sub>2</sub>O<sub>3</sub>, alkali, MgO, ZnO, CuO); while for the LT, the catalyst is Cu/ZnO/Al<sub>2</sub>O<sub>3</sub>, where Cu<sup>0</sup> is the active site and the others textural promoters of Cu dispersion [156,157]. In both cases, the catalysts should undergo controlled reducing pre-treatments in order to activate the catalytic sites, and it is well-known that this pre-treatment largely affects overall performance [158].

Alternative catalysts have been tested and exhibited comparable activities with regards to the standard ones. Namely, Pt based catalysts have been claimed to be good for HT process, whereas Au-based catalysts have shown promising activities in the LT operation. Worth to mention, is the key role of CeO<sub>2</sub> supports, which have arisen and consolidated with leading outlook in WGS catalysts [155,159–161].

#### 1.3.4 The exhaustive CO clean-up in H<sub>2</sub>-rich streams

The residual CO concentration left upon WGS in H<sub>2</sub>-rich streams must be processed in clean-up post-treatments. These are categorized in two

main groups: (1) physical, and (2) catalytic methods, as described in the following.

#### 1.3.4.1 *Physical methods*

Physical methods compile different hydrogen separation techniques, namely: Pressure Swing Adsorption (PSA), cryogenic distillation and membrane separation [162]. Among them, the multi-step PSA process is the most employed in the large-scale industrial hydrogen production in refineries [163]. Following this methodology, the impure  $H_2$  stream is passed through physic adsorbers (zeolite, alumina, or activated carbon), that capture main impurities:  $H_2O$ ,  $CO_2$ ,  $CO$ ,  $CH_4$  and  $N_2$  which are efficiently removed from the gas stream and essentially pure  $H_2$  is left, at expenses of not full recovery values [164]. Basically, the PSA units are based on the capacity of these adsorbents to retain more impurities at high pressures than at lower ones, so the overall process is roughly consisting in five steps: (1) adsorption; (2) concurrent depressurization; (3) countercurrent depressurization; (4) purge; and (5) countercurrent pressurization, although actual industrial version of this process is divided in 11 cyclic steps [163,164]. Therefore, provided the complex experimental set-up required, consisting in poly-bed systems with multiple parallel columns and heavy compressor instrumentation, it is not feasible to adapt PSA procedures in downsize  $H_2$  processor units.

Regarding cryogenic distillation, the separation is undertaken in a low-temperature and high energy demanding process, which is based on the different boiling temperatures of the feed components, since  $H_2$  has a high relative volatility [165]. However, the system itself is not efficient for  $CO$  and  $CO_2$  isolation, so an additional wash column is required. Compared to PSA, higher  $H_2$  recovery is achieved, but the purity of the produced  $H_2$  is moderate [162].

Finally, membrane separation techniques make use of selective permeable barriers from different nature: inorganic (metallic or ceramic), organic (polymeric or biological) and hybrid composites [166] to separate  $H_2$  from impurities in a process forced by diverse phenomena: molecular sieving, Knudsen diffusion, solution-diffusion and surface-diffusion. In general terms, membrane separation presents several advantages when compared to mature PSA and cryogenic procedures, namely: easy and cost-effective operation, low investment costs and low energy consumption. Among different materials, the inorganic type have attracted wider attention, and in particular, Pd membranes are by far the most studied [167,168]. But since Pd is an expensive material, alternative ceramic or polymeric membranes are more convenient for practical reasons. Currently, technical feasibility has already been demonstrated, so the potential role of membranes as part of fuel processing systems depends on the cost issues instead, still challenge pending to address [127,169,170].

### 1.3.4.2 Catalytic methods

Catalytic methods include mainly two processes: (1) Selective CO Methanation (CO-SMET); and (2) Preferential CO Oxidation (CO-PROX), and these have potential real opportunities in low-size fuel processing units, in contrast with the physical approaches. In fact, the DOE support on *on-board* fuel processing had been key driver for these technologies and relevant achievements were provided [139].

The selective CO methanation, ruled by equilibrium from Equation 1.11, involves partial hydrogen consumption to undertake CO hydrogenation to methane, product which does not affect to the fuel cell operation [139,171,172]. Thus, considering that CO content is very low in the initial feeding, the proportional hydrogen consumption derived from CO-SMET is not a relevant issue, while the no-need of additional inlet gas supply is a very positive aspect from CO-SMET process.

CO-SMET catalysts are commonly based on Ru or Ni active metals [173,174] supported on different metal oxides, such as  $\text{TiO}_2$  or  $\text{ZrO}_2$  [175], which are able to achieve the removal CO targets up to the tolerance level from Pt-electrode when the performance is optimal. However, main drawback of CO-SMET is the competitive  $\text{CO}_2$  methanation reaction, which may occur in the same catalytic environment, driving to a large  $\text{H}_2$  consumption provided the significative  $\text{CO}_2$  content.

In practice, the alternative PReferential OXidation of CO (CO-PROX), topic of the present Project Thesis is the preferred catalytic methodology, despite being a more exothermic process, hence operation more difficult to control, since it does not lead to hydrogen consumption [127,132,176,177]. Next section reviews CO-PROX process in detail.

### 1.3.5 The Preferential Oxidation of CO (CO-PROX)

Back to a broad contextualization, the CO-PROX reactor would be situated downstream LT WGS and directly connected to the PEM fuel cell, so the ideal operating temperature is governed by the two frontier processes, that is, in the range from 80 to 250°C. As a *selective* oxidation of carbon monoxide, it is required a continuous air/ $\text{O}_2$  supply to the reactor within extensive control upon the operating temperature, pressure and residence since several undesired side reactions can additionally take place in the reaction mixture.

Principally, the CO oxidation reaction (Equation 1.3) competes with  $\text{H}_2$  oxidation reaction (Equation 1.4), which provokes an efficiency loss provided the fuel consumption.

CO oxidation reaction:

H<sub>2</sub> oxidation reaction:

Furthermore, other side or consecutive reactions may occur from a thermodynamic point of view, such as:

CO methanation reaction:

CO<sub>2</sub> methanation reaction:

Reverse Water-Gas Shift reaction (RWGS):

Particularly, CO and CO<sub>2</sub> methanation reactions described in Equations 1.11 and 1.12, respectively, consume hydrogen and would contribute to the non-controlled emissions. Besides, as exothermic reactions, these could give rise to a thermal run away in the CO-PROX reactor. On the other hand, RWGS (Equation 1.13) is the most undesired side-process since it ruins the achieved clean-up.

Accordingly, since catalytic CO-PROX reaction is manifold, a high selectivity is the critical requirement to establish suitable catalysts for this process [178]. Additionally, the catalyst must be active within the operating CO-PROX temperature window and keep stable performance along lifetime and in long time-on-stream utilization. Besides, it should be compatible with CO<sub>2</sub> and H<sub>2</sub>O and display acceptable performance in these conditions, since these inhibitors would be present in real CO-PROX reaction environment.

Based on these considerations, the catalysis science over the Preferential CO Oxidation reaction has addressed the study and optimization of classical oxidation catalysts, such as Pt, Ru or Rh, which has been extended to other non-noble active metals with promising results. Next section revises the state-of-the art of CO-PROX active catalysts presented so far.

## 1.4 State-of-the-art of the catalytic Preferential CO Oxidation (CO-PROX) reaction

### 1.4.1 General background

The concept of Preferential CO Oxidation (CO-PROX) dates back to the 1920s, when it was recognized the practicability of a catalytic combustion process for the selective removal of carbon monoxide from hydrogen,

targeted to purify H<sub>2</sub> streams for the Haber-Bosch process in the ammonia synthesis [179,180]. Thus, one of the first applied studies was presented by Lamb, Scalione and Edgar, who revealed the potential application of hopcalite catalyst to oxidize 0.5% of carbon monoxide in hydrogen by adding air in a slight excess of oxygen over that required for complete oxidation of CO [181,182]. Hopcalite, a well-known CO removal substance developed during World War I by the US Army as part of respiratory protection equipments [183], consisting in a mixture of amorphous manganese (~60%) and copper (~40%) oxides and small quantities of iron, cobalt or silver oxides [184–186], used to show good CO oxidation performance in dry air, although the presence of moisture seemed to be strongly deactivating.

Nevertheless, despite destabilizing hopcalite structure, the presence of H<sub>2</sub>O in the inlet stream had two secondary positive benefits in the catalytic activity relying on (1) the improved heat dissipation upon the exothermic process occurring, and (2) the thermodynamically hindered H<sub>2</sub> oxidation, which widened hopcalite CO selective operation. Thus, it was precluded the possibility to tune the catalytic performance and separate both oxidation processes, in agreement with the general rule that reducible oxides, such as hopcalite, are reduced at lower temperatures by carbon monoxide than by hydrogen [187].

In fundamental terms, reducible oxides are characterized by their relative facility to exchange oxygen, provided by their moderate energy difference between the lowest empty states in the conduction band with respect to the valence band [188]. Thus, reducible oxides are typically semiconductor d-metal oxides, such as TiO<sub>2</sub>, Fe<sub>2</sub>O<sub>3</sub>, NiO, MnO<sub>2</sub>, CuO or CeO<sub>2</sub>, able to form non-stoichiometric oxides arisen from the variable oxidation state from M<sup>n+</sup> to M<sup>(n-1)+</sup> upon their facile lattice oxygen abstraction [189,190]. In turn, elements from the broad family of reducible oxides present chemical reactivity particularities, which bring relevant impact in their utilization in industrial catalytic processes, specially, those based on oxidation reactions.

Namely, when reducible oxides act as active catalysts, they easily follow the well-reported Mars-van Krevelen (MVK) mechanism [191], where surface oxygen ions from the catalyst are directly involved in the reaction. In result, lattice oxygen is gradually being depleted along with the oxidation reaction course, at expenses of creating anionic oxygen vacancies in the crystal and the partial reduction of the metal oxide. Figure 1.8 depicts key steps in MVK mechanism for a reducible metal oxide catalyst ongoing a general oxidation reaction [192], besides Langmuir-Hinshelwood (LH) mechanism [193] is annexed for comparative reasons.

**Figure 1.8.** Schematization of MVK and LH mechanism key steps for CO oxidation reaction.

As figure 1.8 shows, the anionic vacancies in the lattice should be replenished by an auxiliary oxygen source, such as molecular O<sub>2</sub> gas supply in the reactant mixture, ideally equilibrating lattice oxygen abstraction by its balanced restitution. In turn, in contrast with oxidation catalysis where reaction occurs in dissociatively adsorbed O\* species from O<sub>2</sub> gas phase, in MVK mechanism there may not be a correlation between the reactant oxidation and O<sub>2</sub> dissociation sites. Evidences of MVK mechanism have been extensively presented along decades of well-reported literature by means of different experimental settings, such as MS-monitored pulsed-isotopic experiments for the molecular labeling and traceability of species.

Hence, the positive catalytic features over reducible oxides rely on the fact that the “active” sites are virtually extended to most of the exposed surface, rather than punctual spots where activated adsorbed molecules should locally meet on surface to react. In agreement with this, the improvement in the relative reduction facility (so-called reducibility), would lead to the creation of more active and more reactive sites for the catalytic oxidation, but also a facile and efficient re-oxidation guarantees continuity of the reaction by the regeneration of technically unlimited active sites.

Regarding this, main parameters that determine reducibility in metal oxides is the nature and strength of M – O bonds, the relative energies of the resulting reducible cations, besides characteristic surface topology and surface reconstruction issues upon lattice relaxation, which are in global, determining factors into the overall reactivity in MVK mechanism.

In result, there is a vast research field focused on the improvement of redox properties in solids in order to achieve an optimum catalytic performance, and hopcalite catalyst (amorphous CuMn<sub>2</sub>O<sub>4</sub>) was one of the first examples that, by chance, accomplished with these considerations even before being aware of them. In timeline, a general CO oxidation mechanism upon hopcalite catalyst based on its reduction and latter O lattice uptake was described for the first time by Rogers et al. in 1921 [194], being afterwards confirmed by other authors [195,196] and modeled with kinetic equations in 1970 by Brittan and co-workers [197]. However, despite decades of spread utilization, the reasons for the promoted activity of hopcalite catalyst into CO oxidation remained unclear.

In this regard, Schwab and Kanungo [198] hypothesized in 1977 the solid-state charge transfer in the redox system:  $\text{Cu}^{2+} + \text{Mn}^{3+} \leftrightarrow \text{Cu}^{+} + \text{Mn}^{4+}$  as the driving force for the “anomalous promotion” of the catalytic activity of manganese oxide when mixed with copper oxide. Later, in 1986, Cocke and Veprek [199,200] demonstrated for the first time direct experimental evidences for the existence of that Cu – Mn redox interplay and its critical effect into the encountered hopcalite catalytic activity. Most interestingly, though, the authors remarked the possibility to open-up a general concept of solid-state redox systems and extend it to other systems with potential uses in catalysis, which currently holds large part catalysis research field.

Thus, although hopcalite was being widely used, its limited stability and low activity in ambient conditions of temperature and humidity, triggered to set the focus on different catalytic alternatives towards CO oxidation with a reproducible and durable performance. Likewise, deep fundamental studies brought truly important research outcomes from heterogeneous catalysis science, using CO oxidation as test reaction over different catalyst configurations [201–205], such as the well-reported Pt/Al<sub>2</sub>O<sub>3</sub> or Au/TiO<sub>2</sub>, which showed excellent activity.

However, along with the PEM fuel cell technology revolution, a suitable CO oxidation catalyst was required to operate in presence of large H<sub>2</sub> excess, which actually means a challenge, and the necessity to develop cost-effective and large-scale produced materials for extended application. Thus, as section 1.5.2 reviews, catalytic approaches into the CO-PROX reaction compile mainly three types of catalysts, and they are result of thorough development efforts conducted along decades of research.

#### 1.4.2 Active catalysts for CO-PROX reaction

The most commonly employed active catalysts in the Preferential Oxidation of CO reaction are categorized into three main families, distributed as follows:

Noble metal-based catalysts [206–209], constituted by a variable 0.5–5% w/w content of dispersed noble metal nanoparticles, Pt [210,211], Pd [212], Rh [213], Ir [214], Ru [215,216] into different metal oxide supports, such as Al<sub>2</sub>O<sub>3</sub>, SiO<sub>2</sub>, zeolites, CeO<sub>2</sub> and CeO<sub>2</sub>-derived materials. Furthermore, after the long track record of CO-PROX basis research into this type of materials, several efficient strategies to improve noble metal-based catalysts performance have arisen. Namely, (i) the bimetallic combinations [217], in terms of metal alloying [218] or core-shell architectures [219,220]; (ii) the promotion with reducible metal oxides, mainly iron oxide in Pt-Fe systems [221,222], and Pt-Sn [223]; or (iii) alkali doping [224,225], have been widely reported and thoroughly studied.

In turn, there is vast research literature into the potential application in CO-PROX reaction over noble metal catalysts, which show fairly satisfactory results. By and large, most of these reproduce high CO oxidation activity with acceptable CO selectivity within the 60-150°C framework, as well as good CO<sub>2</sub> and H<sub>2</sub>O compatibility. In contrast, their high expenses are strong limiting agents to their spread implementation. In result, despite large optimization and encouraging rational design achievements, noble metal-derived research outcomes are virtually focused on fundamental research rather than a realistic commercial outputs.

Nano-gold catalysts [226–231], traditionally involving highly dispersed Au nanoparticles into reducible metal oxide supports from variate nature ranging from TiO<sub>2</sub> [232,233], Fe<sub>2</sub>O<sub>3</sub> [234,235], Al<sub>2</sub>O<sub>3</sub> [236], ZrO<sub>2</sub> [237], CeO<sub>2</sub> and CeO<sub>2</sub>-doped materials [238–240]. From the well-reported literature, size control over gold nanoparticles is crucial, as well as the choice of the support results determining for the catalytic performance by means of the tunable Au<sup>δ+</sup> – MO<sub>x</sub> interfacial redox exchange.

After the pioneer work from Haruta *et al.* [229] the catalysis by nano-sized gold gained much attention. For this purpose, gold-based catalysts are particularly interesting provided the low capacity of Au to chemisorb and dissociate hydrogen [241], which turns into excellent CO selectivity in CO-PROX reaction application. However in practice, although working in lower temperature window than noble metals, Au-based exhibit in general incomplete CO conversion, a notorious limited reproducibility on their performance, a rapid decline in CO selectivity and suffer from severe detrimental effects by CO<sub>2</sub> presence [230]. Hence, because of these drawbacks, despite much research efforts so far, the wide instauration of Au-catalyzed CO-PROX systems is not practicable yet, to the best of my knowledge.

Mixed non-noble metal oxides [177,242–245], mainly compiling transition metal oxides, such as Co<sub>3</sub>O<sub>4</sub> [246,247] or CuO [243,248,249], in combination with other major compounds forming binary mixtures in multiple configurations. In this family of CO-PROX catalysts, MVK mechanism takes place in the labile lattice oxygen from the MO<sub>x</sub> active phases, which is promoted upon a facile redox cycle in the intimate interfacial interaction with the other component, mostly used CeO<sub>2</sub> [250]. Thus, it is not trivial to overall discern active sites in this type of catalysts provided the complex nature of the occurring interfacial redox interactions. Interestingly, in contrast with noble metal and gold-based catalysts, the nominal distribution of “active site” with regard to the “support” is absolutely tunable, from the typical low 0.5-10% range in MO<sub>x</sub>/CeO<sub>2</sub> conventional catalysts, in increasing percent up to above 50% in the so-called inverse CeO<sub>2</sub>/MO<sub>x</sub> catalysts [251].

In the case of cobalt oxides, these exhibit optimum performance in terms of CO conversion and CO selectivity, although at high temperatures

CO methanation reaction (Eq. 1.11) becomes dominant process at expenses of CO-PROX [252]. Furthermore, provided their higher expenses with regard to copper oxides, the latter have attracted far more attention, specially, when constituting the binary system: copper oxide – cerium oxide [177,253,254].

Copper oxide – cerium oxide catalysts present excellent activity and selectivity to CO oxidation in the low temperature range of CO-PROX reaction conditions, besides a moderate price, advantage over noble metal-based catalysts; and large stability, in contrast to gold-supported materials. Thus, in addition to its acceptable CO<sub>2</sub> and H<sub>2</sub>O compatibility, these systems have proven to be perfectly suitable for long time operation in real conditions of CO-PROX reaction [255,256].

Hence, provided the great importance relying on their large extended use and encouraging catalytic outcomes as practicable high-performance CO-PROX catalysts, CuO/CeO<sub>2</sub> systems are reviewed in detail in next Section.

## 1.5 The copper oxide – cerium oxide systems

### 1.5.1 General features

The family of CuO/CeO<sub>2</sub> systems constitutes one of the greatest block of catalysts ever studied, with nearly 1000 research papers centred on their catalytic performance in a broad range of targeted applications. Namely, volatile organic compounds (VOCs) oxidation [257], water-gas shift (WGS) reaction [258,259], low temperature CO oxidation [260], preferential CO oxidation (CO-PROX) reaction [261], CO<sub>2</sub> hydrogenation [262], soot oxidation [263], selective catalytic reduction (SCR) of NO<sub>x</sub> [264] or even N<sub>2</sub>O decomposition [265].

As thoroughly reported all over literature, CuO/CeO<sub>2</sub> systems possess unique properties and superior performance provided by synergistic Cu – Ce interactions arising from labile exchange between  $\text{Cu}^{2+} + \text{Ce}^{3+} \leftrightarrow \text{Cu}^+ + \text{Ce}^{4+}$  redox interplay [266–268]. It should be noticed that copper-based catalysts are prone to participate in such redox exchanges when in contact with suitable complementary metal oxide, as demonstrated in the classic hopcalite catalyst occurring between Cu – Mn. In the case of copper oxide – cerium oxide systems, the redox features of bare CeO<sub>2</sub> play an essential role, with the co-existence of Ce<sup>4+</sup>/Ce<sup>3+</sup> species and its capacity to behave as “oxygen buffer” under reducing or oxidizing conditions [269].

In this respect, CuO/CeO<sub>2</sub> composites exhibit enhanced reducibility when compared to single counterparts since, interfacial sites are highly reactive provided the facile oxygen activation which drives to a consequent generation of defects, such as oxygen vacancies [250,270]. Therefore, a

large battery of reported strategies has been devoted to promote interfacial Cu – Ce contact aiming to trigger the redox properties and eventually improve CuO/CeO<sub>2</sub> catalysts performance. Namely, the study upon particle size effect by different procedures [271,272], the formation of conventional or inverse catalysts [251,259], mixed Cu<sub>2x</sub>Ce<sub>1-x</sub>O<sub>2</sub> oxides [255,256] or the doping effect of CeO<sub>2</sub> with different elements [263,273–275], has been addressed in a large list of research papers making use of multiple *ex-situ* and *in-situ* characterization techniques as well as complementary theoretical studies. Next sections review main advances in the state-of-the art for copper oxide – cerium oxide catalysts for the particular application into the Preferential CO Oxidation (CO-PROX) reaction.

### 1.5.2 The CO-PROX reaction mechanism over CuO/CeO<sub>2</sub> catalysts

According to general consensus established by renowned studies [276–278], Cu<sup>+</sup> species are the active CO oxidation sites in CuO/CeO<sub>2</sub> catalysts, whose formation and stabilization would be promoted via Cu<sup>2+</sup> + Ce<sup>3+</sup> ↔ Cu<sup>+</sup> + Ce<sup>4+</sup> redox equilibrium in the labile Cu – Ce interface [279,280]. To date, part of the biggest achievements on the description of accurate CO-PROX reaction mechanism over CuO/CeO<sub>2</sub> catalysts must be acknowledged to the exhaustive work from Prof. Martínez-Arias and co-workers, who consolidated the identification of the postulated active sites by means of conclusive advanced spectroscopic results [281,282], and presented a complete comprehensive description of the whole process. Briefly, it is summarized as follows according to MVK involving redox cycle in copper and cerium species:

#### 1. CO chemisorption in Cu<sup>n+</sup> centers:

#### 2. CO<sub>2</sub> desorption and Cu<sup>n+</sup> reduction:

#### 3. Lattice O restitution and Cu<sup>n+</sup> re-oxidation (two pathways):

##### 3a. Direct mechanism:

##### 3b. Synergistic mechanism (via CeO<sub>2</sub> in Cu – Ce contact):

**Note:** [x] stands for surface O vacancy in either Cu<sub>2</sub>O or CeO<sub>2</sub> lattice; while “Cu<sup>n+</sup> centers” may also refer to Cu<sup>2+</sup> besides Cu<sup>+</sup>, although only the latter has been schematized.

Steps 1-3 compile basic redox cycles involved in CO oxidation mechanism over CuO/CeO<sub>2</sub> catalysts. Prior to the overall interpretation, it is convenient to bear in mind that CuO/CeO<sub>2</sub> catalysts show inherently an average oxidized state, with major Cu<sup>2+</sup> and Ce<sup>4+</sup> components, that is, unless exceptions, their initial natural state in the moment when CO-PROX gas reactant mixture is supplied.

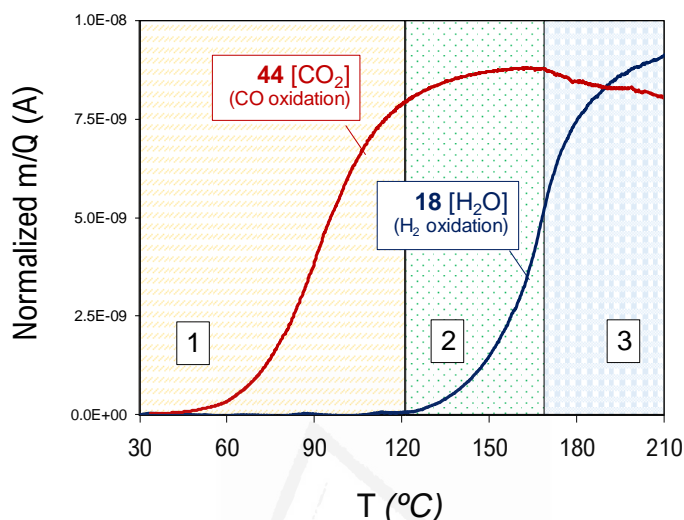

In first instance, carbon monoxide molecules get adsorbed in Cu<sup>n+</sup> sites, either Cu<sup>2+</sup> or Cu<sup>+</sup>, where CO<sub>2</sub> is formed and released upon O lattice abstraction and consequent Cu<sup>n+</sup> local reduction [283,284]. In this regard, experimental results on probe molecular adsorption point out that CO chemisorbs much stronger on Cu<sup>+</sup> sites than on Cu<sup>2+</sup> [285], which is attributed to the balance within electronic donation and back-donation phenomena between CO – Cu<sup>n+</sup> entities. Thus, it is expected that CO would prefer to bind Cu<sup>+</sup> species, whose abundance increases along with reaction course by means of the gradual O vacancy formation via MVK mechanism.

According to well-reported analyses, when CO interacts with the CuO/CeO<sub>2</sub> catalytic surface, Cu<sup>+</sup>–CO carbonyl species are formed, which are detected by means of DRIFT spectroscopy as an intense and sharp signal at ~2100 cm<sup>-1</sup>, immediately after CO-PROX gas mixture is fed to the analysis chamber [284]. The early identification of the Cu<sup>+</sup>–CO band reveals the occurrence of a low temperature CO reduction process, proving the high reducibility of the CuO/CeO<sub>2</sub> catalyst as promoted by the Cu – Ce synergistic interaction. Furthermore, the position of such band is highly sensitive to the coordination and electronic density of copper [286], and its evolution with temperature relates with CO oxidation rate [276,278].

Finally, the lattice oxygen abstraction occurring by means of reaction course needs to be restored by molecular O<sub>2</sub> from gas phase (step 3). This process may take place either directly in Cu<sub>x</sub>O, or via Ce –O –Cu labile entities, which constitute the direct or synergistic mechanism for the lattice O recovery [250,270]. In this regard, the prevalence or concurrence between both O-restoration pathways is still a matter of debate, although it is believed to be strongly dependent, among other factors, on crystal-plane exposure between CuO and CeO<sub>2</sub> contacting phases [287,288].

Up to this point, detailed issues are descriptive for pure CO oxidation process with CuO/CeO<sub>2</sub> catalysts. However, in the Preferential CO Oxidation (CO-PROX) reaction there is a large H<sub>2</sub> excess in the (CO + O<sub>2</sub> + H<sub>2</sub>) reactant mixture, which is expected to get involved in the competitive process corresponding to its oxidation (Eq. 1.4). Luckily, as stated before as general rule for reducible oxides, CO is better reducing agent than H<sub>2</sub>. In consequence, CO oxidation should take place at lower temperatures than H<sub>2</sub>

oxidation, which provides a CO selective temperature window corresponding to the difference between the on-sets for CO and H<sub>2</sub> oxidation reactions. Thus, light-off curves in CO-PROX activity tests (CO + O<sub>2</sub> + H<sub>2</sub>) with high-performance catalysts may show three distinguishable regions, though dependent on test conditions:

**Figure 1.9.** MS monitored product signals for 44 (CO<sub>2</sub>) and 18 (H<sub>2</sub>O) from CO-PROX activity test conducted in high-performance catalysts. Three different reaction regimes are discerned.

In the region (1) at lowest temperatures, CO oxidation reaction is the only process taking place, so it is called the *CO selective regime*. Rising the temperature above certain critical point comprises overcoming H<sub>2</sub> oxidation reaction *on-set*, so that it starts taking place in concurrence with CO oxidation reaction during regime (2), so-called the *non-CO selective regime*. In this stage, both processes compete for O<sub>2</sub>, so depending on the inlet O<sub>2</sub> stoichiometric excess, CO conversion should be more or less affected [210,289]. Finally, a farther rising of temperatures reaches regime (3), with an observable average gain of H<sub>2</sub> oxidation reaction in detriment to CO oxidation, provided the higher activation energy for the former process [177]. Depending on experimental conditions, there may not be difference between regimes (2) and (3), in the cases when the start of H<sub>2</sub> oxidation reaction directly leads to a CO conversion fall.

Interestingly, although there is still debate regarding the competitive nature of CO and H<sub>2</sub> oxidation reactions, clear evidences of the key role of copper oxidation state in this regard have been presented [268,276,278,290,291]. For instance, Martínez-Arias and co-workers published truly relevant papers studying CuO/CeO<sub>2</sub> systems by means of CO-PROX *operando* XAS and advanced complementary techniques, which concluded that, though physically sharing copper as catalytic location, CO and H<sub>2</sub> oxidation are activated in different sites. Namely, CO oxidation is

favorable in stable and active surface  $\text{Cu}^{\text{I}}$  species balanced in a  $\text{CuO}$  bulky environment, whereas  $\text{H}_2$  oxidation is claimed to occur massively when metal  $\text{Cu}$  entities are formed in partially reduced  $\text{Cu}_x\text{O}$  particles resulting by the effect of temperature in the reducing CO-PROX atmosphere [278].

Yet, it has been reported the presence of a high excess of  $\text{H}_2$  not only determines the optimum temperature for CO-PROX reactor operation, established in terms of CO conversion / CO selectivity compromise, but also may condition surface chemistry during the ongoing processes [292–294]. As a result, CO-PROX reaction is rather complex, and multiple approaches aiming to tune  $\text{CuO}/\text{CeO}_2$  catalytic performance have been reported so far, as shortly reviewed in next Section 1.5.3.

### 1.5.3 Rational design of $\text{CuO}/\text{CeO}_2$ systems

As shortly described in previous section, research track record on catalytic CO-PROX reaction over copper oxide – cerium oxide systems has enabled to disentangle the specific features implicated in CO-PROX catalytic performance from the abstract  $\text{Cu}$  –  $\text{Ce}$  interaction concept. Namely, a labile cyclability upon  $\text{Cu}^{2+}/\text{Cu}^+$  and  $\text{Ce}^{4+}/\text{Ce}^{3+}$  redox pairs exchange, for the sake of a facile formation of surface oxygen vacancies, and stabilization of the active  $\text{Cu}^+$  states. In turn, the optimization into the preparation of  $\text{CuO}/\text{CeO}_2$  systems with improved performance comprises the enhancement in the efficient contact between  $\text{CuO}$  and  $\text{CeO}_2$  phases, and different approaches have been explored so far.

In this regard, computational studies supported on Density Functional Theory (DFT) basis have demonstrated electronic perturbations when  $\text{Cu}$  ad-atoms are deposited on  $\text{CeO}_2$  crystal surfaces [295–298]. Results indicate that  $\text{Cu}$  loading on  $\text{CeO}_2$  facilitates oxygen vacancy formation, besides it was found that interaction degree is strongly dependent on  $\text{CeO}_2$  exposed facet. Likewise, in  $\text{CeO}_2(111)$ , the most stable and abundant facet in polycrystalline ceria,  $\text{Cu}$  is prone to be stabilized as  $\text{Cu}^+$  [299], whereas in  $\text{CeO}_2(110)$ ,  $\text{Cu}$  ad-atom remains as oxidized  $\text{Cu}^{2+}$ , instead [300]. However, it is hard to assume such pure considerations, though well-shaped, real  $\text{CuO}_x/\text{CeO}_2$  catalysts, which exhibit dissimilar results and declare the intersection between the low-index (110)/(100) terminations as the most reactive positions for CO oxidation [301–303]. Thus, experimental studies devoted to achieve fine control over  $\text{CeO}_2$  nano-shape and morphology [304,305], have enabled the preparation of well-reported  $\text{CeO}_2$  nano-cubes (110), nano-rods (110)+(100), among which, the later intrinsically show the highest relative

abundance of defects and oxygen vacancies in good correlation with their observed improved catalytic performance.

**Figure 1.10.** TEM images of  $\text{CeO}_2$  displaying different nano-shapes.

As alternative approach aimed to improve  $\text{CeO}_2$  unique properties, the effect of the lattice insertion of different elements in  $\text{CeO}_2$  has been well-reported, too, which showed very positive outcomes in the extensive investigations in the Three-Way Catalysts (TWC) field [263,274]. By and large, it is widely known that doping  $\text{CeO}_2$  with suitable foreign cations has several benefits on its bare catalytic features, such as improving the thermal stability and surface reducibility, oxygen storage capacity and oxygen mobility [306]. However, when at practical application for CO-PROX reaction, the effect of  $\text{CeO}_2$  doping in variable cation loading of Zr, Pr, La, Sm, or Tb among others, frequently results detrimental for the overall catalytic performance in most of the studies reported [275,307,308]. In this regard, the postulated arguments to understand this particular behavior rely on the low-temperature intrinsic nature of CO-PROX reaction, being targeted below the  $250^\circ\text{C}$  threshold. Hence, although improved properties by  $\text{CeO}_2$  doping, such as the sintering prevention or the increase in oxygen storage capacity, may result beneficial in applications at higher temperatures, these do not lead to a relevant effect in the CO-PROX thermal window operation. On the contrary, the presence of foreign cations, instead of being positive, is proven to limit the synergistic effect from copper oxide – cerium oxide interactions, hindering the formation of interfacial Cu – O – Ce reactive sites [292], which is a key feature in CO-PROX catalysis.

Conversely, the preparation of inverse  $\text{CeO}_2/\text{CuO}$  catalysts, where copper oxide is main component from the binary system has resulted in positive catalytic features with regards to the conventional  $\text{CuO}/\text{CeO}_2$

configuration, and mixed  $\text{Cu}_x\text{Ce}_{1-x}\text{O}_2$  reference oxides [251,259]. According to theoretical and experimental findings, the disperse  $\text{CeO}_2$  particles in inverse catalysts present much larger  $\text{Ce}^{3+}$  population, thus more oxygen vacancy defects and a greater active oxygen mobility [259]. Likewise, the big-size  $\text{CuO}$  particles in inverse catalysts show more limited reducibility and bulky redox features. Hence, despite easily reaching surface  $\text{Cu}_2\text{O}$  states upon the interfacial contact points with  $\text{CeO}_2$  nanoparticles, these  $\text{Cu}^+$  species are not gradually reduced to growing  $\text{Cu}^0$  local entities as in the conventional design. Instead, the deeper extension from the  $\text{CuO}$  bulky environment prevents farther reduction as it is much more affected by kinetic limitations, and  $\text{Cu}^+$  states are eventually stabilized [251]. This resulted in a highly positive widening of the CO selective regime in CO-PROX reaction conditions as expected according to the postulated mechanism within the role of  $\text{Cu}^0$ , so that  $\text{H}_2$  oxidation reaction *on-set* was efficiently delayed up to higher temperatures.

Finally, other synthetic approaches worth to mention have been presented, too, as the preparation of  $\text{CeO}_2$ -based materials with improved textural properties. For instance, meso-structured  $\text{CeO}_2$  [309–311] or the so-called three-dimensionally ordered macroporous (3DOM)  $\text{CeO}_2$  [312], prepared via colloidal crystal templating on PMMA or PS packed spheres [313,314]. Interestingly, this polymer-templated procedure allows not only to achieve the efficient gas path with largely interconnected wide pores, but also has been related to the creation of a higher population of surface oxygen defects in  $\text{CeO}_2$  [315,316]. Thus,  $\text{CeO}_2$ -based 3DOM samples show a more reactive surface than analogue references, which leads to an improved catalytic performance. However, the synergistic copper oxide – cerium oxide interaction in 3DOM materials has been found to be poor because of the limited Cu – Ce contact in the wide open 3DOM structure, so it is a challenge still pending to address for the improved use of this promising materials.

In this scenario, provided the inherent outstanding performance of conventional  $\text{CuO/CeO}_2$  materials, for instance, prepared by the very simple metal nitrate calcination and impregnation, major part of the complex synthetic attempts to improve  $\text{CuO/CeO}_2$  catalytic properties result either detrimental or negligible in most cases. Nevertheless, outcomes from the multitude of potential approaches to tune critical  $\text{CuO/CeO}_2$  features, eventually mean valuable fundamental knowledge towards an improved CO-PROX application. So, in conclusion, despite the advanced rational design conducted up to date, conventional  $\text{CuO/CeO}_2$  catalyst would be preferred in the hypothetical wide implementation of PEM fuel cell technology, because of simplicity and excellent behavior.

#### 1.5.4 Criticality of cerium oxides and catalytic opportunities for manganese oxides

As detailed in the previous section, CuO/CeO<sub>2</sub> catalysts have demonstrated excellent performance, being appropriate materials to hold multiple catalytic applications without the expensive costs of noble metals. Nevertheless, cerium oxides are not cheap either, whose price in 2018 was globally set near 5500 USD/metric ton [317], in contrast with the easily affordable alumina (Al<sub>2</sub>O<sub>3</sub>) or titania (TiO<sub>2</sub>) supports, averaged in 470 and 140 USD/metric ton units, respectively [318,319].

Regarding cerium oxide market, as in the case for Rare Earth (RE) metal-derived resources, China accounts for about the 90% of global production [320,321], holding an unquestionable supremacy in the global manufacturing and exportation of these high-added value materials, which eventually brings powerful geopolitical interests. Provided that RE mining and production involve very high costs, and dramatic environmental impact via strongly polluting practices, [322,323], no other economies are much interested or do not have the economic facilities to invest in RE metal manufacturing, so China will continue retaining in the future the absolute leadership, controlling the RE metals market price.

In consequence, there is a rising concern regarding RE metals use, which are nowadays present in nearly every electronic device and their demand is dramatically rising [324]. In the particular case of Ce element, it is the most abundant RE metal on Earth's crust, and though current demand is weak, the US Department of Energy considered as *near-critical* the Ce supply risk in the short and medium term [325], highlighting the importance to find alternative material substitutions for the sake of a less critically dependent market.

With current industrial application niche in UV filters, polishing powders, ceramics, phosphors, glasses, pigments, and three-way automotive exhaust emission control catalysts [320], the implementation of ceria-based catalytic technologies in CO-PROX reaction is only partially practicable since near-future strategies are meant to restrict RE use whenever efficient substitutes are available [326]. As a result, potential reliable catalytic alternatives to cerium oxide materials are a strategically pursued, as for the Preferential CO oxidation reaction, among which, manganese oxides have been claimed as promising candidates.

First, in contrast with RE metal resources, mineral manganese oxides are abundant, non-toxic, and environmentally-friendly, besides highly versatile as naturally found in several polymorphs with multiple manganese oxidation states [327].

**Figure 1.10. (a)** Cryptomelane ( $\text{KMn}_8\text{O}_{16}$ ) tridimensional simulation with  $2 \times 2$   $\text{MnO}_6$  octahedra arrangement and intratunnel K species. **(b)** TEM images of cryptomelane nanorods.

From the broad family of manganese oxides, a promising material for catalytic applications is cryptomelane (Figure 1.10), a potassium-manganese mixed oxide derived from  $\alpha$ -hollandite  $\text{MnO}_2$  consisting in a tunneled structure formed by double chains of corner-sharing  $\text{MnO}_6$  octahedra basic units [328,329]. The channel size left in between the  $2 \times 2$  octahedra arrangement is  $0.46 \times 0.46$  nm, and K ionic species and water molecules are hosted inside, compensating charge imbalance by the co-existence of various Mn oxidation states, and providing structural stability, respectively [330,331]. Furthermore, the structure and composition of mineral cryptomelane oxide can be achieved easily by laboratory procedures leading to a synthetic material commonly named as Octahedral Molecular Sieve  $2 \times 2$  (OMS-2) [328,329].

The excellent catalytic aptitude of OMS-2 materials has been extensively reported over a wide range of applications, namely catalysts for volatile organic compounds (VOCs) oxidation [332,333], oxidation of CO [334], catalytic water splitting [335]; as well as in electrochemical supercapacitors [336]; or as electrode in batteries [337]. The unique versatility over cryptomelane-based materials relies on the high porosity, acidity, hydrophobicity, electronic and ionic conductivities, and easy removal of lattice oxygen and recovery [338–340], features provided by the facile redox cycling among  $\text{Mn}^{2+}$ ,  $\text{Mn}^{3+}$ , and  $\text{Mn}^{4+}$  states, leading to an average manganese valence of ca. 3.8 [341,342].

In addition, it is well-known that cryptomelane redox properties can be tuned by means of the introduction of different framework dopants such as Fe [343,344], Ce [345–347], Ni [348–350], Co [347,349,351–354], Ag [355,356], V [357–359] or Cu [360–365], whose effect is dependent on, first, dopant location and distribution, and second, the target Mn species being

substituted in each case, determined by similarities in cation size, charge, and polarizability. From above, the best catalytic improvements have been achieved with  $\text{Cu}^{2+}$  doping, in a curiously interesting analogy with the first hopcalite catalysts. Cu-doping beneficial effect is generally attributed to several factors: (1) the higher electronegativity of Cu, which weakens in a large extent the Mn–O bond in Mn–O–Cu bridges, resulting in the mobility and reactivity of the active oxygen species; (2) the versatile insertion of Cu-rich phase substituting  $\text{Mn}^{2+}$ , fitting into  $\text{CuO}_6$  octahedra, or tunnel  $\text{K}^+$  cations, which increases Mn average oxidation state and provokes crystal structure distortion and the promotion of defects [343,360,366–368]. As a result, Cu-modified cryptomelane materials are more catalytically active systems, though less thermally stable than bare cryptomelane, which is a challenging limitation for their durable utilization in a hypothetical implemented use.

Furthermore, it may be tentatively ascribed certain analogy of Cu-doped cryptomelane with the well-reported  $\text{CuO/CeO}_2$  catalysts, where special interfacial redox properties by means of synergistic effects result in an excellent performance [278,369]. So that, the promising cryptomelane-type manganese oxides are meant to hold a key role in the substitution of catalytic  $\text{CuO/CeO}_2$  systems in certain applications, including CO-PROX reaction. Therefore, a critical analysis of the feasibility of Cu-doped cryptomelane analysis in terms of activity and stability is determinant to ensure its adequate implementation and the potentially efficient substitution of cerium oxides, which has not been presented so far, to the best of my knowledge.

## 1.6 Main objectives of the Project Thesis

Taking in thorough consideration the general contextualization exposed in previous Sections along Chapter 1, this Project Thesis arises with focus on the exploration into green active catalysts for the Preferential Oxidation of CO (CO-PROX) reaction, which is critical step in the exhaustive  $\text{H}_2$  purification processing with current available production technologies.

With the aim to avoid expensive noble metals utilization and the non-stable performance characteristic of nano-gold catalysts, this Project Thesis addresses the study over copper-based catalysts as a target cost-effective potential option to undertake CO-PROX reaction. As a first approach, conventional  $\text{CuO/CeO}_2$  systems have been studied in order to establish a background knowledge upon a high-performance well-reported catalyst. Then, outcomes from fundamental research with  $\text{CuO/CeO}_2$  catalyst are to be taken as reference standards in view of the consideration of their possible substitution by alternative abundant and eco-friendly copper oxide – manganese oxide catalysts, namely  $\text{CuO/Cryptomelane}$  formulations.

Therefore, the main objectives set in this Project Thesis can be synthesized in the following five broad points:

1. *The fundamental study over CuO/CeO<sub>2</sub> systems for the assessment of key mechanistic features and the specific physico-chemical properties that turn into their outstanding performance as CO-PROX catalysts.*

According to this Project Thesis structure and organization, Objective n. 1 is addressed in Chapters 3 and 4, comprising CO-PROX mechanistic studies over pure and doped CuO/CeO<sub>2</sub> catalysts, respectively.

2. *The preparation, characterization and activity testing of alternative CO-PROX catalysts supported on non-RE metal oxides, being CuO/Cryptomelane the particular system under critical evaluation.*

In this regard, Objective n. 2 is mainly aborded along Chapters 5 and 6, with the systematic study of CuO/Cryptomelane stability and regenerative issues in CO-PROX operation conditions, including real performance simulation.

3. *The proposal of a reliable mechanistic study over CO-PROX reaction with the alternative CuO/Cryptomelane catalyst, in analogy with the well-reported on CuO/CeO<sub>2</sub> systems.*

With the aim to tackle Objective n. 3, Chapter 7 comprehends the use of sophisticated non-conventional methods on the study of CO-PROX mechanistic issues in CuO/Cryptomelane catalysts, provided the intrinsic limitations of conventionally extended techniques at their application on this particular material.

4. *The critical comparison between CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalysts in CO-PROX application, in terms of activity and stability in diverse reaction conditions, including the presence of CO<sub>2</sub> and H<sub>2</sub>O inhibitors.*

Regarding Objective n. 4, Chapter 8 compiles relevant data from CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalysts for their direct inter-related evaluation.

5. *The scalability of powdered copper-based active phases in medium-sized monolithic catalysts with improved performance prepared by means of 3D-printing technology.*

In the last instance, Objective n. 5 comprises a technological leap moving from the small-scale powdered catalysts to monolith-supported testing, which is furthermore conducted under a non-conventional approach by 3D-printing, as presented in Chapter 9.

## 1.7 Conclusions

(1) The non-sustainable current energy-related policies are predicted to match inevitably global worldwide development with an increasing rate in GHG emissions unless deep restructuration of energy system is seriously undertaken from now.

(2) Hydrogen deployment as energy vector, although challenging, involves multiple advantages in the decarbonization of the energy system, for instance in fuel cell technology, and mainly, PEM fuel cells.

(3) The fueling requirements for PEM fuel cells comprise  $H_2$  with very high purity degree, as the particularly low (10-100 ppm) CO content, a strong poisons for the necessary Pt-based electrode.

(4) Among the explored CO clean-up processes, the Preferential CO Oxidation (CO-PROX) catalytic reaction is the most feasible and holds promising outlook, specially in portable PEM fuel cell applications with *on-board* fuel processing.

(5) Catalysis research over CO-PROX reaction has resulted in a deep knowledge and the preparation of multiple active phases from diverse nature, namely: noble metal, nano-gold and metal oxides, being the latter the most convenient according to a performance – cost balance.

(6) Copper oxides dispersed in reducible oxides have demonstrated a large potential to conduct catalytic CO-PROX reaction with outstanding results, specially when mixed with cerium oxides and related systems.

(7) The wide range of configurations tested over copper oxide – cerium oxide systems in CO-PROX reaction has allowed to conduct a fine tuning of the process, while optimizing the catalytic performance by means of an enhanced synergistic Cu – Ce effect towards the promotion of the active  $Cu^I$  states.

(8) The geopolitical criticality linked to RE extraction and manufacturing, that affects cerium oxides, is encouraging the pursue of other analogue alternatives to act as an efficient support for the copper active phases.

(9) Manganese oxides are principal candidates in the substitution of cerium oxides provided their high oxygen mobility, oxidation state variability, and proven excellent copper compatibility as in the classic hopcalite catalyst.

(10) Cryptomelane is a mineral potassium-manganese mixed oxide with excellent catalytic features, although its long time operation and stability have not been studied to critically evaluate its wide implementation as CO-PROX catalyst.

# **CHAPTER 2**

## **Methods and techniques description**

Chapter 2 describes the methodology and research approach developed in this Project Thesis, comprising experimental techniques complemented with punctual computational calculations based on Density Functional Theory (DFT). The fundamental principles of each technique, instrumentation, experimental set-ups and specific operation conditions are presented in this Chapter, which will be referred henceforward in all along the Thesis extension.

Universitat d'Alacant  
Universidad de Alicante

## 2.1 Methodology and research approach

This Project Thesis focused on the study of copper-based formulations for their potential application as active catalysts in the Preferential CO Oxidation (CO-PROX) reaction, has fundamentally followed an experimental research approach, although it is complemented with Density Functional Theory (DFT) calculations to either predict or interpret certain experimental data outcomes. As evidenced in the evolution along these last years in current research methodology, a dual theoretical – experimental approach is optimum to reach an in-depth understanding of the studied catalytic reaction.

Hence, aiming to address catalytic CO-PROX reaction with groundbreaking first principles approach, this Project Thesis comprises the utilization of a complete battery of conventional characterization techniques combined with cutting-edge experimental analyses and advanced computational methods for the detailed description of the catalytic systems. Provided the wide range of techniques operated in this Project Thesis, these are categorized and presented in detail in the following sections along this Chapter 2, namely experimental and computational approach.

## 2.2 Experimental methods

The experimental approach deals with the synthesis, characterization and activity testing of active copper-based catalysts in CO-PROX reaction. Thus, the experimental methodology described in the following details: (1) the specific synthetic procedures for the preparation of catalytically active inorganic formulations; (2) the physicochemical characterization techniques employed for the elucidation of particular properties from the prepared materials and their critical interpretation in view of the best catalytic performance; (3) the conductance of CO-PROX catalytic activity tests in order to assess their performance in different simulated operation conditions; (4) advanced studies upon the formulations with best performance for the fine description of the catalytic environment and mechanistic issues.

A brief explanation of main procedures, techniques, equipments and related experimental setup, as well as operation conditions is listed below.

### 2.2.1 Catalyst synthesis

The preparation of the catalytically active materials has been conducted using simple procedures with well-reported good outputs, comparable to more complex and expensive synthetic routes [1]. Roughly, two type of catalysts were prepared during this Project Thesis, namely copper oxide – cerium oxide systems ( $\text{CuO/CeO}_2$ ), and copper oxide – manganese oxide catalysts ( $\text{CuO/Cryptomelane}$ ). Both were targeted with

nominal 5% weight (wt.) of Cu (metal) loading, as a compromise loading taken from preliminary studies, and copper incorporation was carried out by means impregnation on each previously prepared support.

Although each Chapter already will describe specific experimental modifications when corresponding, in general terms a common procedure can be detailed as follows for each formulation:

#### 2.2.1.1 Preparation of CeO<sub>2</sub> support

CeO<sub>2</sub> was obtained via thermal decomposition of cerium(III) nitrates treated in muffle furnace following the chemical process described in Equation 2.1, which occurs in the range between 220-280°C [2–4]:

The resultant metal oxide from this simple procedure, CeO<sub>2</sub> or so-called *ceria*, is expected to present polycrystalline structure, irregular particle size and an heterogeneous micro- and meso-porosity left upon the exhaust gases release [5]. The thermal treatment in air conditions was conducted according to a “flash” calcination procedure, method that emerged to improve compositional homogeneity in citrate gel route for the preparation of Ce<sub>x</sub>Zr<sub>1-x</sub>O<sub>2</sub> mixed oxides [6]. Likewise, “flash” calcination involved the direct introduction of metal precursor Ce(NO<sub>3</sub>)<sub>3</sub>·6H<sub>2</sub>O (Panreac) in a preheated muffle at 200°C in static air, stabilization for 1 hour and later gradual temperature increase (10°C/min) up to the calcination temperature (500°C) [7,8].

According to previous research conducted in the group [8], the choice of these particular conditions does not affect much on the properties of the resultant CeO<sub>2</sub> with regards to a counterpart sample prepared through analogue conventional ramp calcination program (room temperature to 500°C at 10°C/min pace), but these were established as routine to standardize the synthesis protocol.

#### 2.2.1.2 Preparation of Cryptomelane (K<sub>x</sub>Mn<sub>8</sub>O<sub>16</sub>)

Synthetic cryptomelane was prepared following an adaptation from the so-called *reflux* method, procedure described by DeGuzman et al. [9,10], ruled by the redox chemical process occurring between KMnO<sub>4</sub> and Mn<sup>2+</sup> species to produce amorphous MnO<sub>2</sub> forms (Equation 2.2), which in very controlled conditions transform into cryptomelane (K<sub>x</sub>Mn<sub>8</sub>O<sub>16</sub>) nano-rods.

Particularly, cryptomelane catalysts presented in this Project Thesis were prepared establishing the following protocol: 11 g of manganese(II) acetate (Aldrich) are dissolved in 40 g of water and the pH of the solution

gets fixed at 5 using glacial acetic acid. This acid solution is heated and maintained at the boiling temperature under reflux for 30 min. After that, a solution of 6.5 g of potassium permanganate (Aldrich) dissolved in 150 ml of water is added to the boiling mixture, where a brownish slurry is immediately formed, and it is kept under reflux with vigorous stirring for 24 hours. The resulting substance is filtered, washed with distilled water until neutral pH and dried at 120°C overnight. Finally, the dark-colored solid is calcined at 450°C for 2 hours to obtain cryptomelane.

### 2.2.1.3 Preparation of CuO-supported catalysts

Once supports were prepared, the grinded powders were impregnated with an aqueous solution of copper salt precursor, namely  $\text{Cu}(\text{NO}_3)_2 \cdot (5 \cdot \frac{1}{2})\text{H}_2\text{O}$  (Panreac), prepared by dissolving the corresponding amount to a target 5% nominal wt. Cu content in the accurate volume, according to *incipient wetness impregnation* methodology. Thus, the volume of the solution is restricted to by the volume of the matrix to be filled, so that the solution is entirely drawn into the pores by capillary forces and merely coating in a thin film solution the external particle surface, which enables the maximum control on the metal loading and leads to higher yields with regards to *excess*, or *wet*, *impregnation* [11]. Accordingly, the precisely determined volume of copper salt precursor solution was added dropwise to the powdered supports, and homogeneity was ensured by physical mixing during the careful impregnation process. Hence, depending on the support, the impregnated samples were treated different successive steps:

On the one hand, in CuO/CeO<sub>2</sub>, the impregnated sample was directly introduced in a preheated muffle furnace and followed “flash” calcination procedure equivalent as the detailed in Section 2.2.1.1 for the preparation of bare CeO<sub>2</sub>. Conversely, CuO/Cryptomelane catalyst was obtained after drying the impregnated solid at 110°C overnight and calcined in conventional ramp program in a rate of 5°C/min up to 400°C for 5 hours.

## **2.2.2 Catalyst characterization techniques**

In catalysis science, it is well-known that the physicochemical features of the catalytic materials, such as composition, porosity and crystalline structure, surface chemistry and redox properties correlate well their performance in reaction tests and determine their latter application. Thus, in order to understand the catalytic activity behavior and discern optimum features, a systematic characterization study on the potential active samples is crucial. With this aim, the prepared catalytic materials, fresh or spent samples when convenient, were characterized in detail by means of a battery of complementary techniques.

Next sub-sections present main characterization techniques used in this regard all along this Project Thesis, describing briefly their fundamentals, experimental settings and selected operation conditions.

#### 2.2.2.1 *Physisorption of gases*

Heterogeneous catalysis is a phenomenon governed by a solid-gas interaction, where reactants in the gas phase are activated on the surface of powders or porous catalytic materials. Hence, since it is essentially meant to occur on the boundaries of the catalyst surface, the proper determination of accessible surface area and textural properties of potential active materials is a key issue in catalysis science, which is most generally conducted by means of gas physical adsorption techniques [12,13].

In general terms, physical adsorption comprises the accumulation of certain species from an interacting gas phase on the surface of solids, which is leveraged by uncompensated surface cohesion molecular forces. Since the capacity of gas retention is dependent on the solid porosity and accessible surface, the precise determination of pressure changes upon gas exposure at constant temperature, which brings adsorbed volume, enables the calculation of the surface area by means of the application of accurate mathematical models.

Today, most commonly used approach on texture characterization is N<sub>2</sub> adsorption at -196°C, although other adsorbates in alternative conditions are well-reported as well as long as these are chemically inert on surface, present spherical shape when adsorbed and preferably possess a high saturation pressure at the operative temperature. In the case of N<sub>2</sub> adsorption, the mathematical determination of surface area is most often conducted by means of the application of equations derived from the Brunauer-Emmett-Teller (BET) theory [14], widely considered the standard method for this purpose over the last 50 years, though depending on critical approximations that may not be fully representative of each particular studied system.

The linear expression of BET equation is defined by Equation 2.3, being “p” the pressure; “p<sub>0</sub>” the saturation pressure (1 bar in N<sub>2</sub>, -196°C conditions); “C” a parameter related to the adsorption heat; “n” the number of adsorbed moles per catalyst gram; and “n<sub>m</sub>” is the so-called monolayer capacity expressed in moles/g, which is considered to be directly dependent on total surface area according to the fundamentals this theory (S<sub>BET</sub>, expressed in m<sup>2</sup>/g), as described in Equation 2.4.

$$\frac{\frac{p}{p_0}}{n \cdot \left(1 - \frac{p}{p_0}\right)} = \frac{1}{n_m \cdot C} + \frac{(C - 1)}{n_m \cdot C} \cdot \frac{p}{p_0} \quad \text{Eq. 2.3}$$

$$S_{\text{BET}} = n_m \cdot a_m \cdot N_A \cdot 10^{-21} \quad \text{Eq. 2.4}$$

In the latter,  $N_A$  stands for Avogadro's constant ( $6.022 \cdot 10^{23}$  molecules/mol), whereas " $a_m$ " is the occupied area of a single adsorbed molecule (defined as  $0,162 \text{ nm}^2$  for  $\text{N}_2$  in  $-196^\circ\text{C}$ ) [15]; and  $10^{-21}$  is a unit conversion factor. Thus, by the appropriate graphical representation of Equation 2.3, " $n_m$ " is mathematically calculated, enabling  $S_{\text{BET}}$  determination by Equation 2.4.

The textural characterization of the catalysts prepared for this Project Thesis, was conducted using a volumetric Quantachrome Autosorb-6B instrument, that determines adsorbed volume in an automatic multi-measurement process ruled by systematic vacuum and filling steps at different tunable adsorbate pressures ( $0 < p/p_0 < 1$ ) supplied (Figure 2). Prior to analysis, the samples were processed to clean the targeted surface in a degassing unit for the removal of adsorbed ambient  $\text{CO}_2$  and  $\text{H}_2\text{O}$  molecules by means of a heating treatment at  $150^\circ\text{C}$  in vacuum for 6 hours.

**Figure 2.1.** Degasification (left) and adsorption (right, Quantachrome Autosorb-6B) instruments to record  $\text{N}_2$  adsorption isotherms  $-196^\circ\text{C}$ .

The representation of adsorbed volume against partial pressure " $p/p_0$ " on both adsorption and desorption branches, from increasing and decreasing adsorbate pressures recorded output data, respectively, comprises the so-called *adsorption isotherm*.  $\text{N}_2$  adsorption isotherms may be categorized in 6 main types according to standard IUPAC classification depending on the overall shape, whereas hysteresis loop defines different sub-types, too [16]. Thus, the visual interpretation of adsorption isotherms provides valuable information on the assessment of textural properties of porous materials, revealing key insights on pore size distribution, surface area, and adsorbate-adsorbent affinity.

Regarding porosity characterization, three broad pore types are mainly considered in terms of average radii size, which eventually determine different adsorption mechanisms. Namely, these are mainly discerned on micro-pores (with radii below 2 nm); meso-pores (radii in the 2 – 50 nm range); or macro-pores (for pores with radii larger than 50 nm), among which, micro-pores exhibit the strongest adsorption potential so their determination is of special interest [16]. Hence, the Dubinin-Radushkevich equation (Equation 2.5), based on the fundamentals of Polanyi's equipotential surfaces model [12], enables the calculation of micro-pore volume on the adsorbent solid.

$$\log V = \log V_0 - D \cdot \log^2 \left( \frac{p}{p_0} \right) \quad \text{Eq. 2.5}$$

Where, “V” is the adsorbed volume on liquid state at different particular relative pressures, “p/p<sub>0</sub>”; “D” is a dimensionless parameter defined by adsorbent-adsorptive affinity; and “V<sub>0</sub>” stands for the micro-pore volume per gram of solid, target variable obtained via simple mathematical operation after the proper graphical representation.

In certain cases when considered interesting, CO<sub>2</sub> adsorption isotherms at 0°C were performed as well in analogue Quantachrome Autosorb 6 instrument. The corresponding V<sub>0</sub> values, attributed to the so-called *ultra micro-pores* (with radii narrower than 0.7 nm) were determined in complement with V<sub>0</sub> from N<sub>2</sub> adsorption (that accounts for pore radii in the 0.7 – 2 nm range, because of intrinsic diffusion restrictions of N<sub>2</sub> molecules at -196°C) [17]. Thus, N<sub>2</sub> complemented with CO<sub>2</sub> adsorption brings a more complete characterization on the micro-pore range, particularly useful in highly micro-porous materials.

#### 2.2.2.2 X-Ray Diffraction (XRD)

The sample characterization by means of X-Ray Diffraction (XRD) provides information regarding the crystalline features of the prepared catalytic materials. The technique is based on the optical interference phenomenon known as *diffraction*, occurring when X-ray beams are reflected in preferential directions when they reach the surface of a solid with certain degree of ordering, roughly being approximated as a periodic array of atoms. The recorded directions from diffracted X-rays and their relative accumulation in a determined incident angle range comprises an X-ray diffractogram, which is characteristic from particular lattice geometries, type and form of atoms aggrupation in a crystal structure.

As a diffraction basic principle, X-ray need to accomplish the *Bragg's law* defined by Equation 2.6, so diffraction angles depend on the interatomic distances accordingly:

$$n \cdot \lambda = 2 \cdot d \cdot \sin \theta \quad \text{Eq. 2.6}$$

Being, “d” the characteristic interplanar atomic distance; “λ” the radiation wavelength; “n” an integer number, and “θ” the diffraction angle from scattered X-rays (rad).

Thus, XRD allows to identify crystalline structures by the comparison with standard diffractogram patterns, such as the provided by the Joint Committee on Powder Diffraction Standards (JCPDS) cards database, currently known as the International Centre for Diffraction Data® (ICDD). Furthermore, XRD also permits to discern lattice distortions from their corresponding standard crystal structures, mainly produced by the presence of defects. Hence, XRD results particularly interesting in the case of Cu-supported catalysts, as enables the assessment on Cu ions location, whether inserted or segregated, by considering the lattice distortion upon Cu loading with regards to bare supports.

For CuO/CeO<sub>2</sub>, lattice distortion is easily guessed by changes on the lone characteristic lattice parameter, “a”, reported to be 0.5411 nm for bare fluorite-type cubic CeO<sub>2</sub> crystals [1]. For cubic crystal arrangements, interplanar spacing “d” is defined in terms of “a” as expressed in Equation 2.7, being (111) the plane typically used in calculation for CeO<sub>2</sub> since it turns into the most intense diffraction peak:

$$\frac{1}{d^2} = \frac{h^2 + k^2 + l^2}{a^2} \quad \text{Eq. 2.7}$$

Conversely, cryptomelane, though presenting an irregularly distorted tetragonal crystal structure, can be approximated as K<sub>1.33</sub>Mn<sub>8</sub>O<sub>16</sub> in a tetragonal crystal structure that exhibits two characteristic lattice parameters, namely “a” and “c”, which are reported as 0.9866 nm and 0.2872 nm, respectively [18]. The general formula that describes interplanar spacing on tetragonal crystal structures is expressed by Equation 2.8. Thus, the more complex calculation of “a” and “b” requires of two interplanar “d” spaces, obtained from two different diffraction peaks, choosing for practical convenience, (211) and (310) in this Project Thesis.

$$\frac{1}{d^2} = \frac{h^2 + k^2}{a^2} + \frac{l^2}{c^2} \quad \text{Eq. 2.8}$$

On the other hand, XRD can also provide the crystallite size (D) when calculated by means of the Scherrer’s equation (Equation 2.9) [19,20].

$$D = \frac{K \cdot \lambda}{\beta \cdot \cos \theta} \quad \text{Eq. 2.9}$$

Being, “K” is the Scherrer’s constant or shape factor; “ $\lambda$ ” is the radiation wavelength; “ $\theta$ ” is the diffraction angle; and “ $\beta$ ” the full-width at half maximum (FWHM) of a selected peak (rad), generally the most intense. Alternatively, more accurate crystallite size results can be achieved by means of Williamson-Hall’s method [20,21], which separates FWHM contribution from crystal size and strain (distortion in a non-uniform crystal by atom displacement), as expressed by Equation 2.10:

$$\beta = \beta_{\text{size}} + \beta_{\text{strain}} = \frac{0.9 \cdot \lambda}{D \cdot \cos \theta} + \frac{4 \cdot \Delta d \cdot \sin \theta}{d \cdot \cos \theta} \quad \text{Eq. 2.10}$$

Where  $\Delta d$  is the difference of the d spacing corresponding to a typical peak, and D can be obtained by the graphical representation of  $\beta \cdot \cos \theta$  plotted against  $4 \cdot \sin \theta$ .

In this Project Thesis, X-ray diffractograms were recorded in a Bruker D8-Advance diffractometer (Figure 2.2) provided with Göebel mirror with an X-ray generator Kristalloflex K 760-80F, using Cu K $\alpha$  radiation ( $\lambda = 1.540598 \text{ \AA}$ ). Diffractograms were recorded at  $2\theta$  between  $10^\circ$  and  $90^\circ$ , with a step size of  $0.05^\circ$  and a time of 3s per step, and “K” factor was set as  $K = 0.94$ , as reported in literature for CeO<sub>2</sub> and cryptomelane-type materials.

**Figure 2.2.** X-ray diffractometer Bruker D-8 Advance.

#### 2.2.2.3 Raman spectroscopy

The fundamentals of Raman spectroscopy are well-known and can be revised elsewhere [22]. By and large, it is based on the inelastic interaction of a monochromatic light beam of incident frequency ( $\nu_0$ ), with a material with under an oscillating electric field, that produces new frequencies on the dispersed photons ( $-\nu_k$  and  $+\nu_k$ ). This set of  $\nu_k$  values, so-called Raman frequencies are characteristic of each structure, and the difference:  $\nu_k - \nu_0$  is

referred to as Raman shift, which is generally represented in terms of wavenumber ( $\text{cm}^{-1}$ ) in Raman spectra.

Hence, Raman spectroscopy is a technique aimed to study the crystalline structure of solid materials, being frequently used as good complement to the information obtained by means X-ray diffraction. In comparison, Raman spectroscopy presents higher sensitivity to lattice parameter changes or crystalline disruption upon the presence of defects, but the analyzed depth volume in the sample is much lower than XRD, which is total, as considered a “bulk” analysis.

In this Project Thesis, Raman spectroscopy has been used to study the structure of bare  $\text{CeO}_2$  and cryptomelane supports, assess possible structural effects by CuO loading, and the catalyst stability study on the analysis of spent samples. To this aim, Raman spectra were recorded in a Jasco NRS-5100 dispersive Raman using laser source of He:Ne (632.8 nm) and a 4-stage Peltier cooled CCD detector. The Raman signal was collected using a 20x (0.45 NA) objective. The laser power, calibrated on the sample, was kept close to 1.8 mW. The Raman shift was calibrated using the  $520.7 \text{ cm}^{-1}$  line of crystalline silicon prior to the sample analysis.

**Figure 2.3.** LabRam (Jobin-Ivon) Raman dispersive spectrometer, with confocal microscope.

On the other hand, *in-situ* Raman spectroscopy experiments are presented in Chapter 3 comprising the spectra measurement in selected well-controlled temperature and atmosphere conditions. These analyses were recorded using a LabRam Jobin Ivon Horiba instrument (Figure 2.3) with He:Ne laser excitation source and a high temperature chamber with a stable flow and temperature control. Namely, 100 ml/min flow of He was fed to the chamber containing the catalyst and heated up to  $250^\circ\text{C}$  in a slow rate doing steps at certain temperatures, 50, 100, 150, 200 and  $250^\circ\text{C}$  keeping sufficient time to achieve representative stationary stage. Then, Raman spectra were recorded at each temperature in (1) He; and in (2) CO-PROX reaction environment, after switching inlet gases to CO-PROX gas mixture: 2% CO, 2%  $\text{CO}_2$ , 30%  $\text{H}_2$ , while keeping a total flow of 100 ml/min. Comparing

*in-situ* He and CO-PROX Raman spectra at each recorded temperature allows to establish a correlation with structural changes on reaction course, associated with the ongoing CO-PROX reaction mechanism, which is highly valuable information.

#### 2.2.2.4 Temperature Programmed Reduction (TPR)

Temperature Programmed Reduction (TPR) is, in general terms, an experimental procedure that allows to determine the reducibility of the catalysts, and comprises the monitorization of a solid-gas reaction in a reducing atmosphere alongside rising temperature. The thermal response of the material in certain reducing gas environments ( $H_2$  or CO mixtures, mainly) is registered in profiles plotted versus temperature, exhibiting characteristic peaks related to the kinetics of the transformation and the nature of the studied systems.

In the case of CuO-supported catalysts, TPR experiments are essential element among the battery of catalyst characterization techniques, since provide concluding evidences regarding the degree of synergistic interaction between CuO and the metal oxide support. As stated in Chapter 1, the positive synergistic effect upon Cu loading on the support, either  $CeO_2$  or cryptomelane, should result in the promotion on the labile redox exchange between Cu – Ce, or Cu – Mn species, respectively, leading to an activation in the reduction susceptibility, also seen as an improved *reducibility* [23,24]. In turn, reduction events registered in TPR profiles should exhibit a proportional shift towards lower temperatures when compared to the corresponding constituting individual phases. Furthermore, provided that CO oxidation is expected to occur by means of a Mars-van Krevelen (MVK) mechanism, involving lattice oxygen, the relative facile reduction of the catalysts correlates well with the catalytic activity.

**Figure 2.4.** Micromeritics Pulse Chemisorb 2705 equipment.

In this Project Thesis, Temperature Programmed Reduction experiments were conducted with  $H_2$  ( $H_2$ -TPR) in a Micromeritics Pulse Chemisorb 2705 instrument (Figure 2.4) establishing the following conditions: 40 ml/min of 5%  $H_2$ /Ar gas mixture flowing through a quartz fixed-bed reactor containing 40 mg of catalyst in a heating ramp of 10 °C/min up to 950°C. A cryogenic bath prepared by isopropanol/liquid nitrogen mixture traps  $H_2O$  from the outlet stream to protect the Thermal Conductivity Detector (TCD), that is used to determine  $H_2$  consumption alongside temperature increase.

A CuO reference sample, provided by the instrument manufacturer, was used to quantify the amount of  $H_2$  consumed in the experiments in order to check the extension of the reduction in the catalyst.

#### 2.2.2.5 Temperature Programmed Desorption (TPD)

Temperature programmed desorption (TPD) experiments were performed to study the retention capacity of  $CO_2$  and  $H_2O$  in catalyst, since these are, respectively, the products from CO oxidation and  $H_2$  oxidation reactions, occurring in the CO-PROX reaction environment. In this regard, the higher amount of retained  $CO_2$  and  $H_2O$ , and the greater stability of these surface intermediate species may be tentatively associated with a less efficient product desorption in CO-PROX reaction conditions. Therefore, the interaction with new reactant molecules would be hampered by the presence of blocking species in the active sites.

In general terms, TPD experiments consist in the analysis and quantification of released species by the effect of heating a sample in inert atmosphere. Being from particular interest,  $CO_2$  and  $H_2O$  retention capacity were estimated in this Project Thesis by their total release upon the inert heating after an appropriate saturation step is conducted on the catalyst sample. Additionally, the effect of concomitant  $CO_2$  and  $H_2O$  chemisorption was studied by means of  $CO_2 + H_2O$  co-addition in the saturation step.

Briefly, the specific performed protocol was: 80 mg of catalyst was placed in a tubular quartz reactor coupled to mass spectrometer (MS) Pfeiffer Vacuum OmniStar for the outlet gases analysis and TPD profile construction. Firstly, a cleaning surface pre-treatment was conducted at 400°C for 30 min in a 100 ml/min flow of Ar. Then, a saturation step with the selected gases was carried out, which consisted of heating the catalyst at 150°C and keeping that temperature for 1 hour under 100 ml/min of 10%  $CO_2$ /Ar (for  $CO_2$ -TPD), 5%  $H_2O$ /Ar (for  $H_2O$ -TPD) or 10%  $CO_2 + 5\% H_2O$ /Ar (for  $CO_2+H_2O$ -TPD). After that, the gas mixture was switched to Ar, and once  $CO_2$  and  $H_2O$  signals were stabilized, the reactor was heated from 150°C up to 650°C following a ramp of 10°C/min in 100 ml/min of Ar.

#### 2.2.2.6 X-Ray Photoelectron Spectroscopy (XPS)

X-Ray Photoelectron Spectroscopy (XPS), is a highly useful characterization technique in catalysis research since it provides information regarding chemical composition and electronic environments on a solid surface, analyzing up to few nanometers depth. In fundamental terms, it is based on the excitation and emission of most internal electrons from surface atoms by the interaction with a monochromatic X-ray beam. As established in the *photoelectric effect* basic principles, the energy of the released electrons must be the difference between incident X-ray energy and the energy which they were bonded to the atom, so-called *binding energy* (BE).

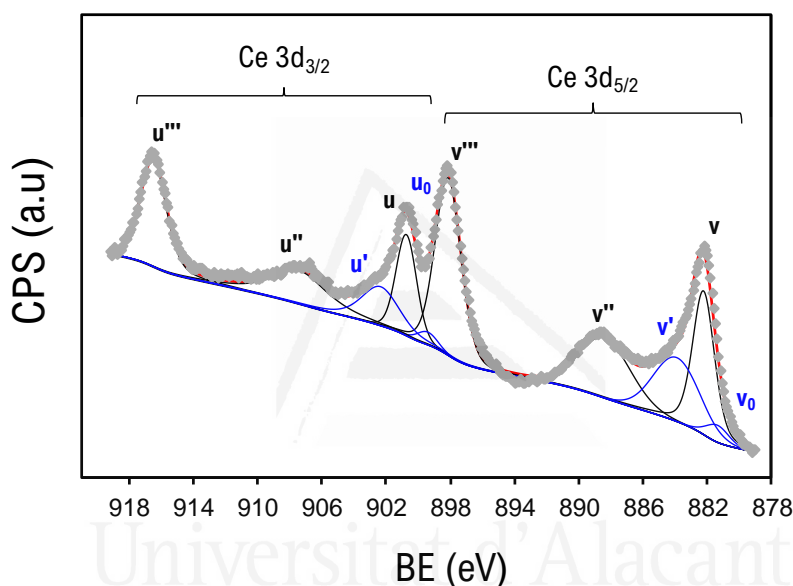

**Figure 2.5.** Fully automated X-ray Photoelectron spectrometer K-Alpha from Thermo-Scientific.

In this Project Thesis, X-ray photoelectron spectroscopy (XPS) analysis was performed by using an automated K-Alpha spectrophotometer (Thermo-Scientific) equipped with a high-resolution monochromator yielding a focused X-ray spot with a diameter of 400  $\mu\text{m}$ , at 3 mA x 12 kV. XPS spectra were collected using a  $\text{AlK}_{\alpha}$  X-ray source (1486.6 eV), and the alpha hemispherical analyzer was operated in the constant energy mode and pass energy of 50 eV (Figure 2.5). Charge compensation was achieved with the system flood gun that provides low energy electrons and low energy argon ions from a single source. The pressure in the chamber analysis was kept at the UHV values of  $5 \cdot 10^{-10}$  mbar, and binding energies were adjusted using the C 1s transition, appearing at 284.6 eV. Binding energy values measured are accurate to  $\pm 0.2$  eV.

Thus, the detailed analysis on specific XPS transitions allow to discern different electronic contributions for a given element with characteristic BEs on distinct well-known energy ranges in the XPS spectrum. Namely, targeted regions under analysis in the whole battery of studied catalysts have been:

C1s (280-300 eV); O1s (525-540 eV); Cu2p (925-965 eV); Ce3d (870-925 eV); Mn2p (630-660 eV); and K2p (290-230 eV). Although the detailed analysis on each region is properly explained when corresponding XPS results are presented along next Chapters 3-10 from this Project Thesis, a brief introductory discussion on the complex Cu2p and Ce3d XPS region analysis and must be presented at this point for the sake of clarity in future data interpretation.

On the one hand, Figure 2.6 displays a representative example of the characteristic Ce3d XPS spectrum, including the assignment of the multiple contributions based on the standard nomenclature provided by Burroughs [25].

**Figure 2.6.** Characteristic Ce 3d XPS spectrum with assignation on the different contributions, displayed in **(blue)** for  $\text{Ce}_2\text{O}_3$ ; **(black)** for  $\text{CeO}_2$  species.

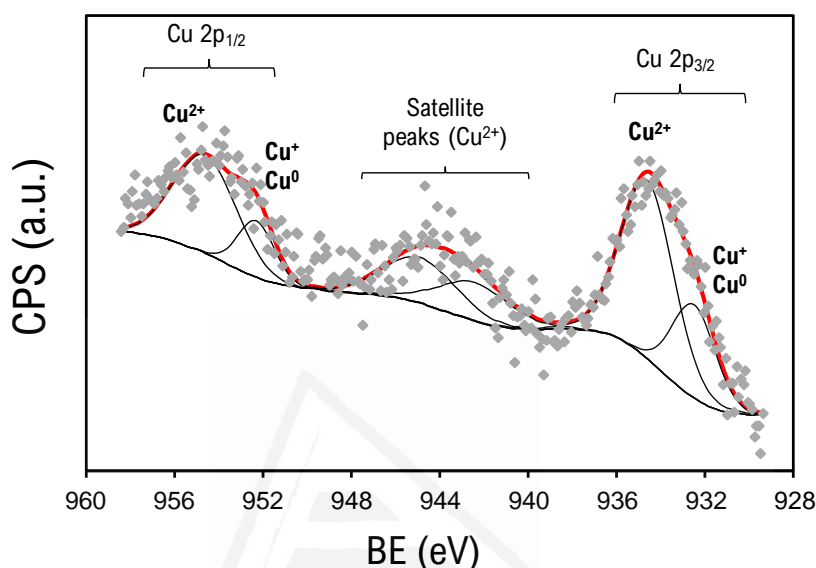

The XPS spectrum of the  $3d_{5/2}$  Ce level is composed of three compounds for  $\text{CeO}_2$  ( $v$ ,  $v''$  and  $v'''$ ) and two compounds for  $\text{Ce}_2\text{O}_3$  ( $v_0$  and  $v'$ ). However, because of spin-orbit coupling ( $3d_{5/2} + 3d_{3/2}$ ), the whole 3d level for Ce comprises ten structures under the same spectrum, corresponding to  $(v + u)$  terms, which unfortunately display small energy separation between them [26]. Thus, despite being truly complex to analyze, the quantification of  $\text{CeO}_2$  and  $\text{Ce}_2\text{O}_3$  relative proportion allows to estimate the fraction of reduced  $\text{Ce}^{3+}$  in the catalyst [27], as described by the formula in Equation 2.11:

$$\text{Ce}^{3+} = \frac{\text{area}(v_0 + v' + u_0 + u')}{\sum \text{area}(v + u)} \quad \text{Eq. 2.11}$$

In this regard, although surface Ce species may be reduced by the intrinsic UHV operating conditions of XPS experiment, the establishment of

a correlation between reduced  $\text{Ce}^{3+}$  fraction in a series of  $\text{CeO}_2$ -based catalysts enables to infer the presence of oxygen defects at surface, which is highly valuable information in view of the understanding of its catalytic performance on CO-PROX reaction.

On the other hand, characteristic Cu2p XPS region exhibits much simpler spectrum, as shown in Figure 2.7.

**Figure 2.7.** Example of Cu2p XPS spectrum with assignation on different species,  $\text{Cu}^0$ ,  $\text{Cu}^+$ , and  $\text{Cu}^{2+}$ .

Figure 2.7, shows a representative example of Cu2p XPS spectrum, exhibiting the characteristic broad  $\text{Cu}2p_{3/2}$  and  $\text{Cu}2p_{1/2}$  peaks, and the characteristic  $\text{Cu}^{2+}$  shake-up satellite which is used by some authors to provide qualitative fashion establishing a linear relation main  $2p_{3/2}$  peak [29,30]. The latter is composed by two contributions assigned to (1)  $\text{Cu}^+$  and/or  $\text{Cu}^0$ , at lower BE; and (2)  $\text{Cu}^{2+}$ , at higher BE, in agreement with standard values reported for pure copper species, as presented in Table 2.1 [28,31].

**Table 2.1.** Standard values obtained for Cu species by XPS and Auger spectroscopy analysis [28].

Compound	Cu $2p_{3/2}$ peak maximum Eb (eV)	Cu LMM Auger peak maximum Ek (eV)	Modified Auger parameter (eV) ( $\alpha'$ )
Cu(0)	932.6	918.6	1851.5
$\text{Cu}_2\text{O}$	932.2	917.0	1849.2
CuO	933.8	917.6	1851.3

Notice that Cu2p<sub>3/2</sub> peak could be theoretically deconvoluted into three components, attributed to Cu<sup>0</sup>, Cu<sup>+</sup> and Cu<sup>+2</sup> contributions, but instead, a two-peak fitting is presented. The reason is the very little statistical peak position separation between Cu<sup>0</sup> and Cu<sup>+</sup> species, which does not allow their resolution with lone XPS characterization [28,32]. However, a widely used analytical approach is to roughly discern between *oxidized* (Cu<sup>2+</sup>) and *reduced* (Cu<sup>+</sup> and Cu<sup>0</sup>) copper species, using the precise representative constrains on BE, FWHM and peak-shape parameters.

Likewise, further resolution among the three copper species is possible if XPS characterization is complemented by Auger spectroscopic analysis of CuLMM line, where Cu<sup>0</sup> and Cu<sup>+</sup> display maximum separation, as Table 2.1 shows. However, the most extended and accurate criteria for total elucidation on copper species takes into account the calculation of the modified Auger parameter ( $\alpha'$ ) to be compared with tabulated values, and/or its latter positioning in a Wagner plot representation when the reported dataset for similar compounds is available [33,34]. The modified Auger parameter ( $\alpha'$ ) is defined by Equation 2.12:

$$\alpha' = E_B (\text{Cu}2p_{3/2}) + E_K (\text{CuLMM}) \quad \text{Eq. 2.12}$$

Being, “ $E_B (\text{Cu}2p_{3/2})$ ” the BE from Cu2p<sub>3/2</sub> XPS peak, and “ $E_K (\text{CuLMM})$ ”, the kinetic energy (KE) from Auger CuLMM line, calculated as indicated by Equation 2.13:

$$E_K (\text{CuLMM}) = \text{AlK}_\alpha - E_B (\text{CuLMM}) \quad \text{Eq. 2.13}$$

Where “ $\text{AlK}_\alpha$ ” stands for the source X-ray energy (1486.6 eV); and “ $E_B (\text{CuLMM})$ ” is the BE of Auger CuLMM line.

#### 2.2.2.7 Transmission Electron Microscopy (TEM)

The TEM microscope uses the transmission/scattering of the electrons produced upon the irradiation of a high energy electron beam on a thin sample (maximum thickness 100 nm), to form images, the diffraction of electrons to obtain information about the crystal structure and the emission of characteristic X-rays to determine the elemental composition of the sample. This technique allows to determine the morphology of the sample (size and position of the microcrystals or the particles) and also the crystallography (position of the crystal planes, study of defects, as well as chemical composition of the material).

TEM characterization was performed using a JEOL (JEM-2010) microscope, equipped with a detector (Oxford, model INCA Energy TEM 100) for microanalysis Energy-Dispersive X-ray Spectroscopy (EDS) (Figure 2.8). A few droplets of an ultrasonically dispersed suspension of the catalyst

in ethanol were placed in a copper grid with lacey carbon film and dried at ambient conditions.

**Figure 2.8.** JEOL (JEM-2010) microscope.

#### 2.2.2.8 Scanning Electron Microscopy (SEM)

SEM provides morphological and topographical information of the solids surface. To obtain an image of the surface, it is scanned with a very thin electron beam with high energy that gives several types of signals as retro-dispersed electrons, secondary electrons, etc.

Catalysts were characterized by SEM in a Hitachi S-3000N microscope with a secondary electrons detector, a retro-dispersed electrons detector and X-ray detector (XFlash 3001, Bruker) for microanalysis (EDS) and chemical mapping (Figure 2.9).

**Figure 2.9.** SEM Hitachi S-3000N microscope.

### 2.2.3 CO-PROX activity tests

Catalytic Preferential CO Oxidation (CO-PROX) reaction activity tests were performed in an atmospheric pressure fixed-bed reaction system coupled to gas chromatography (GC), according to the experimental set-up displayed in Figure 2.10.

**Figure 2.10.** Experimental set-up for the CO-PROX catalytic activity tests.

In each experiment, a regular 100 ml/min flow of gas reactant mixture (2% CO, 2% O<sub>2</sub>, 30% H<sub>2</sub>), set by means of Mass Flow Controllers (Bronkhorst) was fed to a quartz reactor (16 mm inner diameter), where 150 mg of the powdered catalyst sample were placed (GHSV = ~30,000 h<sup>-1</sup>). Catalytic tests were performed in a slow-pace heating ramp of 2°C/min up to 250°C, which comprises near-stationary conditions according to preliminary assays. Reaction progress, *i.e.* product evolution, was monitored by means of a GC HP model 6890 Plus Series equipped with two columns: (1) Porapak Q 80/100 for CO<sub>2</sub> and H<sub>2</sub>O separation; and (2) Molecular Sieve 13X for O<sub>2</sub> and CO separation, coupled to a TCD detector for the outlet gases analysis and generation of light-off curves.

Thus, for the convenient comparison on the catalytic performance among the battery of prepared active samples, the catalytic parameters: CO conversion ( $X_{CO}$ ); O<sub>2</sub> conversion ( $X_{O_2}$ ) and CO selectivity, or selectivity to CO<sub>2</sub> formation (Sel) were determined along the temperature profile being defined as in the following Equations 2.3-2.5:

$$X_{CO} = \frac{p_{CO_{in}} - p_{CO_{out}}}{p_{CO_{in}}} \quad \text{Eq. 2.3}$$

$$X_{O_2} = \frac{p_{O_2_{in}} - p_{O_2_{out}}}{p_{O_2_{in}}} \quad \text{Eq. 2.4}$$

$$Sel = \frac{1}{\lambda} \cdot \frac{p_{CO_{in}} - p_{CO_{out}}}{p_{O_2_{in}} - p_{O_2_{out}}} \quad \text{Eq. 2.5}$$

Where,  $p_x$  stands for partial pressure of gas “x”, either CO or O<sub>2</sub> in the inlet (in) or outlet (out) stream. On the other hand,  $\lambda$  corresponds to O<sub>2</sub> stoichiometric excess, which was set to  $\lambda=2$  in routine experiments, comprising a double O<sub>2</sub> feeding with regard to the required for the total CO consumption. Extensive research on the effect of  $\lambda$  parameter demonstrated that it critically determines CO oxidation activity and residual H<sub>2</sub> oxidation [35,36], being in general optimum when takes values in between 1-2.

Reproducibility of CO-PROX activity tests was proven by performing repeated tests, which typically exhibit average error below 2%. Furthermore, when considered convenient, successive reaction runs were conducted to test catalyst stability upon cyclability, besides long time-on-stream experiments to discard or determine catalytic activity loss in a continuous operation regime at certain chosen temperatures.

Finally, the effect of (1) CO<sub>2</sub>, (2) H<sub>2</sub>O and (3) CO<sub>2</sub>+H<sub>2</sub>O in the catalytic activity was studied by means of the introduction of, either separated or together, 9% CO<sub>2</sub> and 5% H<sub>2</sub>O in the reactant gas mixture feeding. In analogy with CO+O<sub>2</sub>+H<sub>2</sub> experiments, the total flow was kept in all cases as 100 ml/min balanced with He and temperature rose following a 2°C/min ramp up to 200°C.

## 2.2.4 Advanced characterization techniques relevant in mechanistic studies

### 2.2.4.1 Operando DRIFTS

The reaction mechanism was studied in a Fourier Transform Infrared Spectrometer Shimadzu (IR Tracer-100) with a Harrick reaction cell coupled to a EcoSys-P mass spectrometer. The reaction cell was designed to allow the reaction gas mixture (2% CO, 2% O<sub>2</sub> and 58% H<sub>2</sub> balanced with He; 50 ml/min) to pass through the catalyst bed (100 mg without any diluent) with the gas exit at the bottom.

The catalysts were first pre-treated at 400°C for 15 min in a flow of air, and the reaction cell was cooled afterwards to room temperature while maintaining the air flow. A background spectrum was recorded for each catalyst at room temperature after this cleaning step, and then, air was replaced by the reaction gas mixture and the temperature was raised at 5°C/min while infrared spectra were recorded at 10°C intervals. Each spectrum was obtained as an average of 75 scans, measured from 4000 to 1000 cm<sup>-1</sup> with a resolution of 2 cm<sup>-1</sup>. The background spectrum of each

catalyst was subtracted from those obtained under reaction conditions, and therefore, the features observed can be attributed to surface species formed or depleted during the reaction rather than to the catalysts structure.

#### 2.2.4.2 *Operando XAS and NAP-XPS*

Near-Ambient Pressure X-ray Photoelectron Spectroscopy (NAP-XPS) is a highly sophisticated technique that allows to elucidate the surface reactivity and structure in real environments. Compared to XPS traditional measurements, in UHV, NAP-XPS may reveal dramatic differences when working under realistic operation conditions in order to get information during the reactions or processes of interest. This cutting-edge technique has huge relevance and impact in heterogeneous catalysis science and is being used in top catalysis research since the last years.

The X-ray photoemission spectra in CO-PROX reaction conditions were recorded at the NAPP branch from the modifiable beamline CIRCE using ALBA Synchrotron Light Source by means of a PHOIBOS NAP150 energy analyzer from SPECS [37]. For each analysis, two different photon energies were used, being: (1) 1082 and 1372 eV for Ce3d and Cu2p region; (2) 972 and 722 eV for O1s and C1s, providing a variability in the surface depth sensitivity, according to the corresponding estimations on mean free paths (MFP) in the solid structure of CeO<sub>2</sub>-based materials.

**Figure 2.11.** NAP-XPS CIRCE beamline in ALBA Synchrotron (March 2019).

The CuO/CeO<sub>2</sub> catalyst was pelletized with a gold mesh to prevent from surface charge and, providing at the same time, an Au4f reference for the peak position of XPS analysis. Catalytic activity of the gold mesh was experimentally ruled out. The CO-PROX reacting mixture: 1% CO, 1% O<sub>2</sub>, 30% H<sub>2</sub>, 30 mL/min balance N<sub>2</sub> was dosed into the analysis chamber by means of a leak valve and controlled with a Puregas UHV gas inlet system (SPECS). During the NAP-XPS experiments the pressure was kept constant at 1 mbar and the CO-PROX reaction course was monitored with a mass

spectrometer (MS) installed in the second stage of the differential pumping system of the analyzer. For each temperature, the spectra were recorded after MS signals stabilization once achieved stationary state.

Near Edge X-ray absorption (NEXAFS or XAS) measurements at the Cu L edge (930-950 eV) were performed in Total Electron Yield mode measuring sample current at each temperature after the series of NAP-XPS scans using the same experimental conditions.

#### 2.2.4.3 $^{36}\text{O}_2$ pulse isotopic experiments

The capacity of a metal oxide catalyst to exchange oxygen under a fluctuating oxidizing-reducing atmosphere is tightly linked to its ability to produce labile surface oxygen species with enhanced reactivity on MVK-ruled chemical reactions, such as in the case of CO-PROX reaction. Thus, the molecular labeling of such exchangeable oxygen species and its traceability in ongoing chemical processes, may provide crucial information regarding the catalyst performance and reveal the different factors governing the mechanism of reaction.

Isotopic exchange experiments were carried out with  $^{36}\text{O}_2$  by means of an injection valve with a loop (100  $\mu\text{l}$ ) and two high sensitivity pressure transducers. The experiments were carried out in a fixed-bed tubular quartz reactor with 80 mg of catalyst in a constant 20 ml/min of 1% CO, 30%  $\text{H}_2$  balanced He feeding mixture. The exhaust gases were monitored with MS and the  $^{36}\text{O}_2$  pulses (Isotec, 99%; 100  $\mu\text{l}$  and 9 psi) were injected at 75, 100 and 150  $^\circ\text{C}$  once achieved signals stabilization. Prior to this, several pulses of Ar (100  $\mu\text{l}$  and 9 psi) were used as a test to confirm reproducibility of the method.

## 2.3 Computational approach

### 2.3.1 Density Functional Theory (DFT)

Density functional theory (DFT) is one of the most commonly used computational tools to study and predict properties of isolated molecules, bulk solids or interfaces, such as crystal surfaces [38]. DFT principles are based on the Hohenberg-Kohn and Kohn-Sham Theorems, which consider electrons as uniformly distributed around the nuclei, comprising the so-called *electron density*, which is mathematically expressed as a *functional*, that is a function of other functions [39–41].

For periodic DFT calculations, such as crystal structures or crystal surfaces, a *plane wave* basis set, introduced by the treatment of the Bloch's Theorem, is very commonly used to solve Kohn-Sham equations, which require trial functions. Accordingly, plane waves describe electrons that travel through the real space along the repeatedly unit cell, with spacing equal to the lattice constant. However, it is much easier to represent the interaction of plane wave's periodicity with the reciprocal lattice instead, by the analysis of a set of k-points in the Brillouin zone space referred for a number of wavefunctions.

In this regard, there are several software packages able to use plane wave basis sets to calculate electronic properties of solids, such as the Vienna Ab-initio Simulation Package (VASP) [42]. Likewise, DFT computational calculations are performed by means of the set of specific input parameters carefully chosen that: (1) define the nature and particularities of the calculations and; (2) provide a representative description of the real studied systems. Therefore, a deep knowledge of the working catalytic environments is absolutely required to reproduce good theoretical results.

As stated in the overview and general introduction to the methodology undertaken along this PhD Thesis, though mostly comprised of experimental activities, computational studies regarding solid-gas interactions specific catalytic surface properties have been also conducted in order to gain complementary information. Next Section reviews main aspects of the computational approach followed in this research.

### 2.3.2 Computational details

Calculations have been conducted by means of periodic density functional theory (DFT) using the Perdew–Burke–Ernzerhof (PBE) exchange-correlation functional, as implemented in the Vienna Ab-Initio Simulation Package (VASP) code. The core electrons of Ce, Cu and O ions have been described using projector augmented wave potentials, while the valence states were represented by plane-waves with a kinetic cut-off energy

of 500 eV. In the particular case of Ce, a Hubbard U corrective term has been added to the DFT calculated energies (DFT+U) for the on-site correction of electrons in the orbital 4f, as described in literature.[6-8]

Copper oxide and cerium oxide catalysts have been modelled as surface slabs built from the corresponding bulk structures. The geometry of the CuO, Cu<sub>2</sub>O and CeO<sub>2</sub> bulk crystal structures were optimized using a  $\Gamma$ -centred k-point grid of 5 x 5 x 5, and the equilibrium lattice parameter fitted to the Birch-Murnaghan equation of state.

From the optimised bulks, the most exposed surface facets have been prepared, namely CuO(111), Cu<sub>2</sub>O(111) and CeO<sub>2</sub> (111) planes, by the adequate crystal cleavage. Surface slabs are set as thick enough to ensure there is minimal interaction between the top and the bottom, and a sufficiently large (ca. 15 Å) vacuum gap perpendicular to the surface is added to minimize the interaction between periodic slabs in the z-axis. Geometry optimizations of slabs with a  $p(2 \times 2)$  periodicity have been performed using a  $\Gamma$ -centred k-point grid of 3 x 3 x 1.

The catalysts resting state has been assessed by computing ground energies of clean slabs. Afterwards, the effect of introducing structural modifications, such as the abstraction of lattice oxygen ions in precise positions and different electronic rearrangements has been studied. On the other hand, adsorption energies for CO and H<sub>2</sub> molecules have been computed, too.

## CHAPTER 3

# Into the Preferential Oxidation of CO reaction mechanism over CuO/CeO<sub>2</sub> catalyst

Chapter 3 reviews main significative advances achieved so far into the CO-PROX reaction mechanism study over CuO/CeO<sub>2</sub> catalysts, tested and fully characterized through a battery of techniques: N<sub>2</sub> physisorption at -196°C, XRD, H<sub>2</sub>-TPR and Raman spectroscopy, proving inherent synergistic Cu-Ce effects, which turn beneficial into the ongoing MVK mechanism as demonstrated by pulse O<sub>2</sub>-isotopic exchange and *in-situ* Raman spectroscopy. Additionally, cutting-edge experimental techniques for the detailed molecular mechanism dilucidation are presented herein. Namely, CO-PROX *operando* NAP-XPS, and XANES experiments, reveal altogether clear evidences of CeO<sub>2</sub> very surface reduction, assigned to the role of CeO<sub>2</sub> in oxygen assistance to Cu<sub>x</sub>O in Cu – Ce interfacial points, when highly reduced Cu<sub>x</sub>O particles are inefficiently undertaking direct O<sub>2</sub> uptake at advanced CO-PROX reaction degrees. Finally, complementary DFT calculations confirm that lattice oxygen restitution by O<sub>2</sub> gas phase should be at first directly favored in Cu<sub>x</sub>O when partially oxidized, but then via CeO<sub>2</sub> when Cu<sub>x</sub>O particles are reduced at surface by the effect of the reaction course. Since reoxidation issues in CO-PROX reaction have been rarely addressed, this Chapter presents relevant insights for the state-of-the-art in the CuO/CeO<sub>2</sub> catalysts study.

### 3.1 Introduction

CuO/CeO<sub>2</sub> catalysts are well-studied materials with excellent properties towards multiple catalytic applications such as: volatile organic compounds (VOCs) oxidation, water-gas shift (WGS) reaction, low temperature CO oxidation, preferential CO oxidation (CO-PROX) reaction, CO<sub>2</sub> hydrogenation, soot oxidation, selective catalytic reduction (SCR) of NO<sub>x</sub> and N<sub>2</sub>O decomposition [1–3]. The origin of the great catalytic skills of CuO/CeO<sub>2</sub> relies on the synergistic metal-support interactions, which are rather complex redox effects induced on both CuO and CeO<sub>2</sub> in the interfacial contact points between these phases.

Regarding the particularities of CO-PROX reaction, the specific positive features resulting from Cu – Ce interaction in CuO/CeO<sub>2</sub> catalysts are: the formation of surface oxygen vacancies, the labile electron exchange between Cu<sup>2+</sup>/Cu<sup>+</sup> and Ce<sup>4+</sup>/Ce<sup>3+</sup> redox pairs, and the promotion and stabilization of Cu<sup>I</sup> active sites [4–6]. Furthermore, it has been well-reported how CO conversion depends on the ease for the formation of stable and active surface Cu<sup>+</sup> species, whereas H<sub>2</sub> oxidation is claimed to occur massively when metal Cu entities are present by the effect of the temperature in the reducing CO-PROX atmosphere [4,7–9].

As a consequence, to achieve the optimum CO oxidation rate performance in CO-PROX reaction, it is required to keep an operation temperature with a CO conversion and CO selectivity compromise. In this regard, attempts towards the enhancement into the catalytic CO-PROX reaction operation are focused on the separation along the temperature profile between the on-set of both CO and H<sub>2</sub> oxidation processes, by means of the maximization of the Cu<sup>+</sup> species stability via different approaches [10,11]. Since Cu<sup>+</sup> species are being gradually reduced by the effect of the ongoing CO oxidation reaction, their efficient reoxidation by the feeding O<sub>2</sub> gas is crucial to maintain the catalytic performance. Hence, reduction and reoxidation processes occur at the same time during reaction course in quick and labile equilibria. Nevertheless, provided that CO-PROX reaction rate is accelerated with temperature, the average between both processes eventually leads to the extension of the Cu<sub>x</sub>O reduction and therefore, the selectivity loss.

Thus, with the aim to improve Cu<sup>+</sup> stability and endurance to total reduction, the reoxidation step should be studied and facilitated by means of catalyst optimization. In this regard, the strongly interacting CeO<sub>2</sub> support should play a key role given its great lattice oxygen mobility and large oxygen storage capacity (OSC). Nevertheless, few studies are certainly focused on the oxidation process and little is known about the ongoing mechanism of the O restitution route, which could take place wether directly to Cu<sub>x</sub>O from O<sub>2</sub> gas or transferred from intimate contacting CeO<sub>2-x</sub> [12].

Chapter 3 presents a detailed mechanistic study into the conventional CuO/CeO<sub>2</sub> catalytic performance, and compiles the use of multiple complementary advanced *in-situ* techniques to keep the molecular traceability of reactants and products during CO-PROX reaction.

## 3.2 Experimental details

### 3.2.1 Catalysts preparation and characterization

The preparation of CeO<sub>2</sub> support and CuO/CeO<sub>2</sub> (5% wt. Cu) catalyst was performed from thermal decomposition of nitrates and incipient wetness impregnation, as detailed in [Section 2.2.1](#) from Chapter 2. These were thoroughly characterized by means of complementary techniques, namely X-ray diffraction (XRD), N<sub>2</sub> adsorption at -196°C, Raman spectroscopy and temperature programmed reduction with H<sub>2</sub> (H<sub>2</sub>-TPR). Further details on experimental settings and specific analysis conditions can be found in [Section 2.2.2](#). from Chapter 2.

### 3.2.2 CO-PROX activity tests and mechanistic studies

Fixed-bed CO-PROX catalytic tests were performed with 100 ml/min of the He-balanced CO-PROX reactant gas mixture: 2% CO, 2% O<sub>2</sub>, 30% H<sub>2</sub> ( $\lambda = 2$ ), 150 mg of sample and a heating rate of 2°C/min from up to 250°C. Further specifications are described in [Section 2.2.3](#). from Chapter 2.

Isotopic exchange experiments were carried out at selected temperatures with <sup>36</sup>O<sub>2</sub> pulsed by means of an injection valve to a reactor containing 80 mg of sample and a flowing mixture of 20 ml/min of 1% CO, 30% H<sub>2</sub>, simulating CO-PROX reaction conditions. The exhaust gases were monitored with MS to track molecular oxygen products after the pulse.

*In-situ* Raman experiments were performed in a high temperature chamber fed with a regular passing flow of 100 ml/min (He or CO-PROX mixture: 2% CO, 2% O<sub>2</sub>, 30% H<sub>2</sub>). At selected temperatures: 50, 75, 100, 150, 200 and 250°C, Raman spectra were recorded in both atmospheres to study structural changes upon exposure to CO-PROX reactant mixture.

Further details are thoroughly provided in specific parts from [Section 2.2.2](#). in Chapter 2.

### 3.2.3 CO-PROX *operando* NAP-XPS and *operando* XANES

The X-ray photoemission spectra in CO-PROX reaction conditions were recorded at the NAPP branch from CIRCE an modulable beamline at the ALBA Synchrotron Light Source [16]. For each analysis, two different photon energies were used, being: (1) 1082 and 1372 eV for Ce3d and Cu2p

region; (2) 972 and 722 eV for O1s and C1s, providing a variability in the surface sensitivity, according to the inelastic mean free paths. The CO-PROX reacting mixture: 1% CO, 1% O<sub>2</sub>, 30% H<sub>2</sub>, 30 mL/min balance N<sub>2</sub> was dosed into the analysis chamber containing the CuO/CeO<sub>2</sub> catalyst by means of a leak valve in a controlled gas inlet system. CO-PROX reaction course was monitored with a mass spectrometer (MS), and for each temperature, the spectra were recorded after MS signals stabilization once achieved stationary state.

Near Edge X-ray absorption (NEXAFS or XAS) measurements at the Cu L edge (930-950 eV) were performed at each temperature after the series of NAP-XPS scans using the same experimental conditions. [Section 2.2.4](#) reviews in deep detail these experiments.

### 3.2.4 Computational activities

Periodic Density Functional Theory (DFT) calculations have been conducted by means of the *Vienna Ab-Initio Simulation Package* code (VASP, version 5.4.1). CuO (111), Cu<sub>2</sub>O (111) and CeO<sub>2</sub> (111) surface slabs were built and optimized, and the energies for the oxygen vacancy formation on the surface slabs was calculated by means of the formula given by Equation 3.1:

$$E_{(O-vac)} = E_{(vac-slab)} - [E_{(slab)} + \frac{1}{2} E_{(O_2)}] \quad \text{Eq. 3.1}$$

Where  $E_i$  stands for the calculated lowest energy level of the optimized corresponding systems.  $E_{(O_2)}$ , ground energy for the O<sub>2</sub> gas molecules, with complicated electronic structure not properly reproduced by DFT, was set as the DFT-corrected energy of  $E_{(O_2)} = -9.9053$  eV, calculated by the formula ruled by Equation 3.2:

$$\text{DFT-corrected } E_{(O_2)} = 2 \cdot [E_{(H_2O)} - E_{(H_2)}] - 2.506 \text{ eV} \quad \text{Eq. 3.2}$$

The computational part is thoroughly described in [Section 2.3.2](#) from Chapter 2.

## 3.3 Results and discussion

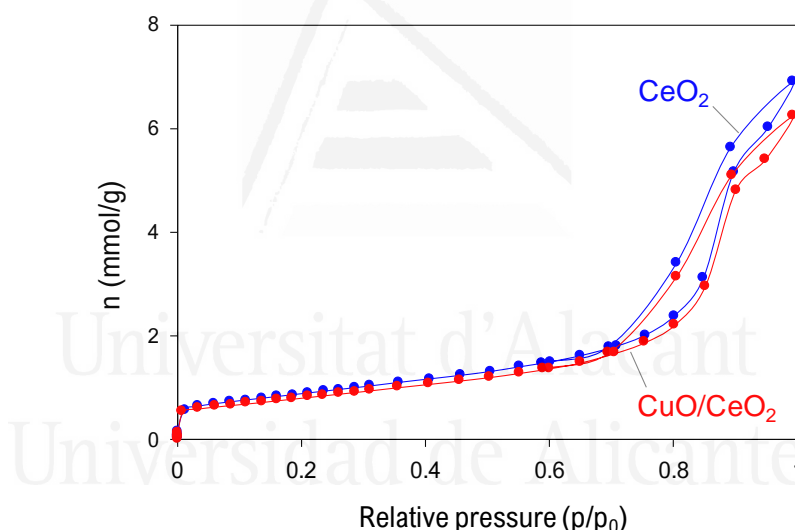

### 3.3.1 Catalyst characterization

The CuO/CeO<sub>2</sub> catalyst was characterized by means of several physicochemical techniques and the most relevant results are presented in Table 3.1. Such analyses were focused on the determination of the effect of CuO loading into the prepared CeO<sub>2</sub> support and these are discussed in the following.

**Table 3.1.** Main characterization results provided from CeO<sub>2</sub> and CuO/CeO<sub>2</sub> catalyst.

Sample	$S_{\text{BET}}$ (m <sup>2</sup> /g)	Cell parameter (nm)	Crystallize size (nm)		% Ce <sup>4+</sup> reduced by H <sub>2</sub> (TPR)	XPS	
			Scherrer	WH		%Ce <sup>3+</sup>	%Cu
CeO <sub>2</sub>	71	0.5420	10	13	20	19.4	-
CuO/CeO <sub>2</sub>	65	0.5411	10	15	17	20.0	5.0

Regarding the textural properties provided by N<sub>2</sub> physisorption analysis (Figure 3.1), both CeO<sub>2</sub> and CuO/CeO<sub>2</sub> show a type-IV isotherm, which is a typical feature from mesoporous materials [20]. Moreover, H2(b) hysteresis loop caused by capillary condensation phenomena evidences broad pore size distribution [21], as expected when following the simple nitrate calcination preparation procedure. On the other hand, the lack of a plateau in the last points of adsorption branch also proves the presence of macroporosity. Comparing between CeO<sub>2</sub> and CuO/CeO<sub>2</sub> samples, the presence of CuO produces a lowering in the calculated BET surface [22] from bare CeO<sub>2</sub>, in agreement with partial pore blocking upon Cu loading.

**Figure 3.1.** N<sub>2</sub> physisorption isotherms (-196°C) from CeO<sub>2</sub> and CuO/CeO<sub>2</sub> samples.

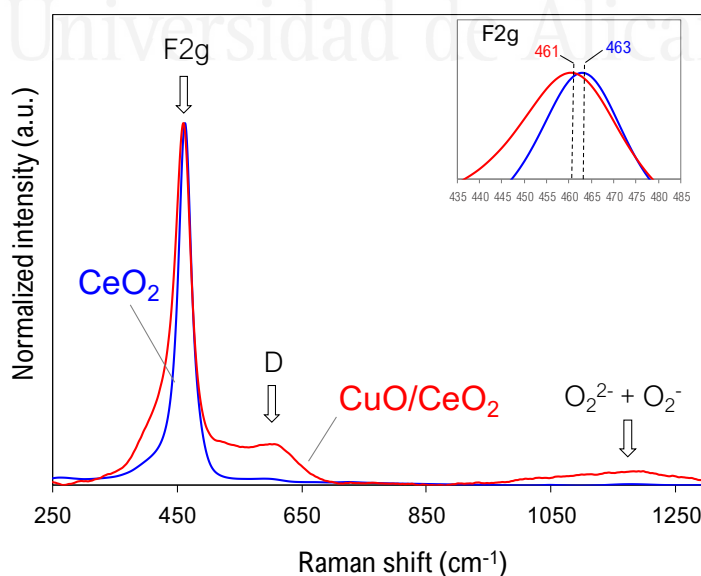

The crystalline features were studied by means of X-ray diffraction (Figure 3.2), where both CeO<sub>2</sub> and CuO/CeO<sub>2</sub> samples display closely identical diffraction pattern fitting with standard CeO<sub>2</sub> fluorite (JCPDS no. 01-075-0120). The presence of CuO is observed by the appearance of characteristic CuO tenorite tiny peaks (JCPDS no. 01-089-2529), which evidence good Cu dispersion on the CeO<sub>2</sub> support. On the other hand, attending to the calculated cubic cell parameter using the (111) peak, the Cu deposition leads to a slight lattice contraction, whereas crystallite size remains practically unchanged. These results are in agreement with well-reported values for CeO<sub>2</sub>-based materials [23] and allow to infer that CuO is

mainly forming a finely disperse segregated phase on the  $\text{CeO}_2$  surface, although minor Cu cations insertion in the  $\text{CeO}_2$  lattice cannot be ruled out.

**Figure 3.2.** X-ray diffractograms recorded for  $\text{CeO}_2$  and  $\text{CuO/CeO}_2$  catalysts. (\*) refers to CuO peaks.

Raman spectra of  $\text{CeO}_2$  and  $\text{CuO/CeO}_2$  samples are presented in Figure 3.3. The intensities have been normalized with the corresponding peak maxima of each spectrum, and since  $\text{CuO/CeO}_2$  spectrum data had much less raw intensity, the bands appear broader than when compared to  $\text{CeO}_2$ .

**Figure 3.3.** Raman spectra corresponding to  $\text{CeO}_2$  and  $\text{CuO/CeO}_2$  catalysts with main band assignments.

The well-reported characteristic Raman spectrum for CeO<sub>2</sub>-based catalysts shows a main Raman line at 463 cm<sup>-1</sup>, corresponding to the active F<sub>2g</sub> mode due to the oxygen symmetric breathing vibration around Ce<sup>4+</sup> ions in the bare fluorite-type CeO<sub>2</sub> lattice [23]. The presence of Cu in CuO/CeO<sub>2</sub> catalyst leads to a red shifting of the F<sub>2g</sub> band to 461 cm<sup>-1</sup> which is explained by the fluorite lattice expansion upon Ce<sup>IV</sup> cations reduction by the Cu<sup>II</sup>/Cu<sup>I</sup> – Ce<sup>IV</sup>/Ce<sup>III</sup> labile redox interaction [3,24]. In agreement with this, the presence of charge-compensating oxygen vacancies is evidenced by additional bands, namely the D bands positioned around 570-600 cm<sup>-1</sup>. Additionally, reactive oxygen species such as peroxides (O<sub>2</sub><sup>2-</sup>) and superoxides (O<sub>2</sub><sup>-</sup>) are detected in weak broad bands in the 950-1250 cm<sup>-1</sup> range, which also corroborates the presence of defects in the lattice and the promotion active oxygen upon Cu loading.

In summary, the presence of Cu seems to activate surface lattice oxygen, as well as promotes the formation of defects, which leads to highly active sites with redox enhanced ability. Comparing with XRD data, since XRD and Raman spectroscopy exhibit different depth sensitivity, it can be concluded that the changes observed upon Cu loading are roughly superficial, being CuO forming segregated phase blocking CeO<sub>2</sub> interparticle spaces.

The reducibility of the catalysts was studied by means of H<sub>2</sub> temperature programmed reduction experiments (Figure 3.4), and these show large differences between CeO<sub>2</sub> and CuO/CeO<sub>2</sub> behavior. The well-reported H<sub>2</sub>-TPR profile from CeO<sub>2</sub> displays two main regions, namely a medium temperature range at ca. 550°C, assigned to surface Ce<sup>IV</sup> cations reduction; and a high temperature process at ca. 800°C, attributed to the reduction of bulk Ce<sup>IV</sup> cations [24], being in both cases Ce<sup>III</sup> the final state of cerium cations.

**Figure 3.4.**  $\text{H}_2$ -TPR profiles from  $\text{CeO}_2$  and  $\text{CuO/CeO}_2$  samples.

On the other hand,  $\text{CuO/CeO}_2$  shows two sharp reduction peaks at low temperature, around 160 and 190°C, attributed to the reduction of finely disperse and large  $\text{CuO}$  particles, respectively [25], although reduction of  $\text{Cu}^{\text{II}}$  in two consecutive steps, first to  $\text{Cu}^{\text{I}}$  and later to  $\text{Cu}^0$ , cannot be ruled out. It should be noticed that bare  $\text{CuO}$  sample starts reducing in the same conditions around 350°C, so the anticipated reduction occurring in  $\text{CuO/CeO}_2$  catalyst must be related to the synergistic  $\text{Cu} - \text{Ce}$  interaction, promoting the reducibility of copper species. Moreover, the labile redox exchange between  $\text{Cu}$  and  $\text{Ce}$  also affects to  $\text{CeO}_2$  surface reduction, as it is much anticipated taking place evolved under  $\text{CuO}$  reduction peaks. The calibrated areas allow to calculate the excess of  $\text{H}_2$  consumed in the two first peaks, and thus, eventually to estimate the total  $\text{Ce}^{\text{IV}}$  reduction in the whole profile. As described in Table 3.1, the reduction of  $\text{CeO}_2$  does not occur in a higher extent when  $\text{CuO}$  is present, but in surface it does take place at much lower temperature, shifting from ca. 550 to below 200  $^{\circ}\text{C}$  with concomitant  $\text{CuO}$  reduction.

In conclusion with the characterization results, the deposition of 5%  $\text{Cu}$  into the  $\text{CeO}_2$  by impregnation conduces to extraordinary redox properties and the facile creation of oxygen vacancies, which are expected to supply great catalytic activity features to the  $\text{CuO/CeO}_2$  catalyst.

### 3.3.1 CO-PROX catalytic activity tests in fixed-bed experiments

Figure 3.5 shows the CO-PROX catalytic activity results of the prepared  $\text{CuO/CeO}_2$  catalyst on a first cycle of reaction without any

pretreatment, which exhibits an excellent behavior in terms of CO conversion and CO selectivity, in agreement with extensive reported studies [1,26,27]. The different profiles present the expected shape according to the employed CO-PROX reaction conditions of experiment, that is, a stoichiometric O<sub>2</sub> excess of 2 ( $\lambda=2$ ) with regards to CO, since it is well-known that  $\lambda$  determines CO oxidation activity and residual H<sub>2</sub> oxidation [28,29]. Provided that bare CeO<sub>2</sub> showed negligible CO conversion in the whole range of CO-PROX experiment, in contrast with CuO/CeO<sub>2</sub>, it is not presented neither discussed anymore along the present Chapter.

**Figure 3.5.** CO-PROX catalytic activity performance with CuO/CeO<sub>2</sub> catalyst in terms of **(black):** CO Conversion ( $X_{CO}$ ); **(blue)** O<sub>2</sub> conversion ( $X_{O2}$ ); and **(red):** CO selectivity profiles (Sel).

Hence, as described in Chapter 1, two different regions must be discerned from the CO-PROX catalytic response displayed in Figure 3.5, namely the CO selective (below ca. 110°C) and the non-selective CO<sub>2</sub> regime (above ca. 110°C), because of the competitive H<sub>2</sub> oxidation reaction. Such critical temperature is determined by H<sub>2</sub> oxidation on-set, process which presents higher activation energy than for CO oxidation [30]. As a result, when rising the temperature, H<sub>2</sub> oxidation process gains relevance and gradually hampers CO oxidation because of the limited O<sub>2</sub> supply, which eventually causes a CO conversion drop above ca. 175°C. These temperature limits determine CO-PROX reaction course and allow to establish an optimum temperature of operation with a CO activity and selectivity compromise, particularly suggested as 110°C for the prepared CuO/CeO<sub>2</sub> catalyst.

Four consecutive CO-PROX reaction cycles were performed and proved the extraordinary stability of the CuO/CeO<sub>2</sub> catalyst along reutilization. Besides, a fifth long time-on-stream experiment allowed to conclude that CuO/CeO<sub>2</sub> also presents excellent stability during continuous CO-PROX operation. Additionally, the inhibition effect by CO<sub>2</sub>, H<sub>2</sub>O and

CO<sub>2</sub>+H<sub>2</sub>O mixture to the CO-PROX activity proving the acceptable tolerance and still great stability of CuO/CeO<sub>2</sub> catalyst. All those results will be presented and discussed in detail along Chapter 8 next to a critical comparison of the real opportunities of the potential CuO/Cryptomelane catalyst.

In the following Sections, thorough CO-PROX mechanistic study with CuO/CeO<sub>2</sub> catalyst by means of several complementary techniques is presented.

### 3.3.2 <sup>36</sup>O<sub>2</sub> pulse isotopic experiments

In order to conduct a detailed study of the enrolment of lattice oxygen towards CO-PROX reaction mechanism, isotopic <sup>36</sup>O<sub>2</sub> pulses were injected in a reactor with CuO/CeO<sub>2</sub> catalyst and flowing CO + H<sub>2</sub> mixture at the set of temperatures: (i) 75°C, representative for low CO conversion regime; (ii) 100°C, representative for high CO conversion and high CO selectivity regime; and (iii) 150 °C, when CO conversion is maximum, but CO selectivity is moderate because of the concomitant H<sub>2</sub> oxidation side reaction.

Figure 3.6 collects quantitative data obtained by the MS analyses after <sup>36</sup>O<sub>2</sub> pulses. First, the overall distribution of the released CO<sub>2</sub> and H<sub>2</sub>O gas products is in agreement with results achieved from fixed-bed experiments as H<sub>2</sub>O contribution increases with temperature according to gradual CO selectivity loss. On the other hand, for all temperatures tested, no O<sub>2</sub> species release was registered, since the strongly reducing conditions of experiment are setting a highly O-deficient surface in CuO/CeO<sub>2</sub> catalyst, which would act as an oxygen trap for the incoming molecules while restoring O sites.

With regards to CO<sub>2</sub> and H<sub>2</sub>O isotopic product distribution, the normalized quantification of each individual isotope molecule has been conducted in separate CO<sub>2</sub> and H<sub>2</sub>O mass balances. The specific MS signals followed after the pulse allow to trace the CO and H<sub>2</sub> oxidation path mechanism. Firstly, with regards to CO oxidation, m/Q 44 CO<sub>2</sub> (<sup>16</sup>OC<sup>16</sup>O non-isotopic) would involve lattice O abstraction and anionic vacancy formation, as an evidence of CO oxidation taking place via Mars-van Krevelen (MVK) mechanism; whereas when m/Q 46 (<sup>18</sup>OC<sup>16</sup>O isotopic), the CO oxidation is taking place involving <sup>18</sup>O\* species adsorbed in the vicinity of CO; and finally, m/Q 48 (<sup>18</sup>OC<sup>18</sup>O isotopic by double exchange) involves a rather complex mechanism consisting of the breakup of a triple C-<sup>16</sup>O bond, and the creation of two double C-<sup>18</sup>O bonds by the interaction of <sup>18</sup>O\* and C\* neighboring sorbed species, assuming O<sub>2</sub> dissociative chemisorption. On the other hand, attending to H<sub>2</sub> oxidation products, it has been monitored m/Q 18 signal (non-isotopic H<sup>16</sup>OH), which evidences H<sub>2</sub> oxidation occurring via MVK mechanism; and m/Q 20 signal (isotopic H<sup>18</sup>OH), attributed to H<sub>2</sub> oxidation with adsorbed <sup>18</sup>O\* species.

**Figure 3.6.** MS integrated signals after <sup>36</sup>O<sub>2</sub> pulse in CO-PROX conditions with CuO/CeO<sub>2</sub> catalyst at 75, 100 and 150°C. **Open symbols:** normalized overall released products (ΣX): CO<sub>2</sub> (**diamonds**); H<sub>2</sub>O (**squares**); and O<sub>2</sub> (**circles**). **Solid symbols:** isotopic distribution among CO<sub>2</sub> (**diamonds**) and H<sub>2</sub>O (**squares**) species.

According to Figure 3.6, clearly most of the released products are non-isotopic (<sup>44</sup>CO<sub>2</sub> and <sup>18</sup>H<sub>2</sub>O) for both CO and H<sub>2</sub> oxidation reactions, which proves, as expected, oxidation mechanisms involving lattice oxygen rather than molecular adsorbed oxygen (MVK). The temperature is due to increase oxygen exchange capacity of the catalyst, *i.e.*, major contribution of non-isotopic products (m/Q 44 + 18) with regard to the isotopic ones (m/Q 46 + 48 + 20), but only a slight increase is observed provided the narrow temperature window for the screening of the pulses.

Nevertheless, the most interesting insights are offered by the analysis of the time-resolved products release since they give relevant information regarding the kinetics of the ongoing processes. Figure 3.7 shows the total O-normalized MS signals evolved after <sup>36</sup>O<sub>2</sub> pulses at 75, 100 and 100 °C.

In general, according to Figure 3.7, the temperature affects the profiles of the products release by a sharpening in their corresponding evolved curves, which is attributed to a faster desorption. However, the most relevant from these profiles is the clear delay in H<sub>2</sub>O release with regards to CO<sub>2</sub>, as well as the large broadening of H<sub>2</sub>O signal. This is consistent with a major surface retention of water molecules due to a less favored H<sub>2</sub>O desorption when compared to CO<sub>2</sub>, which suggests certain degree of H<sub>2</sub>O accumulation on the CuO/CeO<sub>2</sub> catalyst surface during CO-PROX reaction.

**Figure 3.7.** MS signals after  $^{36}\text{O}_2$  pulses in CO-PROX conditions with CuO/CeO<sub>2</sub> catalyst at 75, 100 and 150 °C. The zero-time has been established after the pulse.

In summary, isotopic pulse experiments allow to unequivocally conclude that CuO/CeO<sub>2</sub> catalyst undergoes MVK mechanism in both CO

and H<sub>2</sub> oxidation reactions occurring in CO-PROX environment, which confirms the active role of lattice oxygen. On the other hand, the CuO/CeO<sub>2</sub> catalyst displays an apparent H<sub>2</sub>O retention which could possibly be blocking surface CO oxidation active sites when H<sub>2</sub> oxidation is taking place.

### 3.3.3 *In-situ* Raman experiments

**Figure 3.8.** Raman spectra for CuO/CeO<sub>2</sub> catalyst recorded at different temperatures in 100 ml/min of He (**dotted lines**); and CO-PROX conditions (**solid lines**).

Figure 3.8 shows the Raman spectra recorded at different temperatures in He and CO-PROX conditions, showing the characteristic features corresponding to CuO/CeO<sub>2</sub> as described in Section 3.1. The spectra measured in He provide the inherent lattice thermal expansion, which leads to a shift in the F<sub>2g</sub> band position from 464 to 461 cm<sup>-1</sup> above 200°C, and a gradual increase in the D defects band relative intensity, as evidenced in Figure 3.9.

**Figure 3.9.** D ( $540\text{--}600\text{ cm}^{-1}$ ) /  $F_{2g}$  ( $460\text{ cm}^{-1}$ ) band intensity ratios from Raman spectra at each temperature in He and CO-PROX conditions.

Regarding the effect of CO-PROX atmosphere, the D band grows substantially once overcome  $200^{\circ}\text{C}$ , which proves an extensive oxygen vacancy generation in the  $\text{CeO}_2$  lattice upon the occurring CO and  $\text{H}_2$  oxidation reactions via MVK mechanism in these conditions. Nevertheless, since the on-set for both processes is much lower according to the CO-PROX catalytic activity tests conducted in fixed-bed experiments, it may be tentatively deduced that below certain temperature boundary the  $\text{O}_2$  uptake is efficiently restituting lattice oxygen keeping in equilibrium the processes of oxygen vacancy creation and refilling  $\text{CuO/CeO}_2$ .

On the other hand, the  $F_{2g}$  band in CO-PROX conditions shows a more complex behavior with regards to the control spectra in He atmosphere at the same temperatures. Whereas at  $50^{\circ}\text{C}$  both spectra are identical, at  $100^{\circ}\text{C}$  the CO-PROX spectrum presents a very sharp shifting to the red in the  $F_{2g}$  band which evidences lattice expansion upon partial  $\text{Ce}^{\text{IV}}$  reduction. However, this lattice expansion is not encompassed with the detection of oxygen vacancies in a respective D band. Rising the temperature above  $100^{\circ}\text{C}$  leads to a lowering into the red-shifting of the  $F_{2g}$  band, while D band does not significantly grow. The uncorrelation between the D bands appearance and  $F_{2g}$  band shifting can be tentatively explained as the uncoupling of both Ce cations reduction and oxygen vacancy formation phenomena by the uncompensation of  $\text{CuO/CeO}_2$  reduction process and lattice oxygen abstraction via MVK mechanism because of an inefficient  $\text{O}_2$  uptake. That is to say, at low temperatures the catalyst may be partially more reduced despite O-lattice recovery is taking place. According to this, incoming O would be accommodated in the lattice while Ce cations would remain partially reduced because of the ongoing CO-PROX reaction. When the temperature increases, both processes are better coupled as  $F_{2g}$  band is gradually recovering initial position, and eventually at  $200^{\circ}\text{C}$  fits with He-recorded

spectrum. Finally, at 250°C the catalyst is reduced in average because of the high reaction rate and D band is clearly observed while concomitant F<sub>2g</sub> band red-shifting takes place.

Nevertheless, this observation can be simply anecdotal because of the specific conditions of the experiment, since the sample results locally overheated at the spot irradiated by the laser during the analyses, which may lead to an undefined effect into CeO<sub>2</sub> local reduction, and thus, an overestimation of such process, being more important at lower temperatures. In anycase, the most relevant insights of these characterization results is the observation of extensive CuO/CeO<sub>2</sub> catalyst reduction upon CO-PROX reaction, much after CO and H<sub>2</sub> oxidation reactions begin.

In order to elucidate reversible reduction-oxidation pathways and track the oxidation state of Cu and Ce species in CuO/CeO<sub>2</sub> catalyst during CO-PROX reaction mechanism, NAP-XPS experiments were conducted and the most relevant results are presented in the following Section 3.3.5.

### 3.3.4 CO-PROX *operando* NAP-XPS experiments

CO-PROX reaction conditions were reproduced in a NAP-XPS analysis chamber up to 100% of O<sub>2</sub> conversion ( $X_{O_2}$ ). It should be taken into account that the catalytic activity dependence with temperature is very different for the CuO/CeO<sub>2</sub> catalyst in the *operando* NAP-XPS experiment when compared to the fixed-bed reactor catalytic activity tests or in situ Raman experiments, as Figure 3.10 reveals. Thus, in the CO-PROX *operando* NAP-XPS experiment it is necessary to reach much higher temperatures to achieve total O<sub>2</sub> consumption.

**Figure 3.10.** O<sub>2</sub> conversion ( $X_{O_2}$ ) profiles along temperature for CuO/CeO<sub>2</sub> catalyst in the CO-PROX reaction conditions: (**grey**) 100 ml/min, 1 bar in the fixed-bed reactor tests; (**blue**) 30 ml/min, 1·10<sup>-3</sup> bar in the NAP-XPS experiment.

As previously described, the double S-shaped curve is a consequence of the separate on-sets for CO and H<sub>2</sub> oxidation reactions and the chosen stoichiometric O<sub>2</sub>:CO excess of 2 ( $\lambda$ ). In the case of the NAP-XPS experiment, the on-set for H<sub>2</sub> oxidation is much delayed probably due to the large difference of total working pressure, while CO oxidation apparently remains selective in a wider temperature window. Accordingly, the following XPS spectra showed in this Section 3.3.5 at the selected temperatures are representative of different reaction stages.

On the other hand, the Ce3d and Cu2p XPS regions were scanned using two different photon energies, namely 1082 and 1372 eV, and the information provided from them should be related to the description of different surface depths in the catalyst according to inelastic mean free path (IMFP) calculations [31–33]. Thus, whereas the differences are moderate, it is well-known that the lower the X-ray energy, the lower the IMFP and then, the depth of the analysis. Nevertheless, for the sake of brevity, only the spectra recorded at 1082 eV energies are plotted, whereas compiled results from both energies are included in Table 3.2. Furthermore, XPS spectra were also measured during the oxidizing pretreatment in O<sub>2</sub>/N<sub>2</sub> mixture at 200 °C for comparative reasons, as an indicator of the initial oxidation state of the catalyst. Conversely, the CO-PROX spectra at 50 °C did not show good resolution because of the moderate conductivity of the gas mixture in this low temperature situation, resulting in severe surface charging and eventually, difficult deconvolution fitting because of the broadening of the peaks.

Moreover, the XPS spectra from O1s and C1s regions were measured and analyzed but are not included in the present Chapter for the sake of brevity since their output information is more related to the surface chemistry changes of CuO/CeO<sub>2</sub> catalyst along CO-PROX reaction course, rather than redox processes involved in the mechanism, which is the main topic herein. Briefly, surface oxygen species gain considerably importance during CO-PROX reaction progress, while carbonaceous species tend to disappear. This observation matches with H<sub>2</sub>O accumulation predicted by isotopic experiments, and will be discussed in the following chapters from the results brought by DRIFT spectroscopy, which is the suitable technique to conduct the characterization of sorbed species.

Figure 3.11 shows 3d XPS region (1082 eV) of CuO/CeO<sub>2</sub> catalyst in different conditions and the assignment of the multiple contributions based on the standard nomenclature provided by Burroughs [29]. Hence, the XPS spectrum of the 3d<sub>5/2</sub> Ce level is composed of three compounds for CeO<sub>2</sub> and two compounds for Ce<sub>2</sub>O<sub>3</sub>, so the proper interpretation of partially reduced CeO<sub>2</sub> samples needs to consider the deconvolution of ten structures under the same spectrum, according to spin-orbit coupling (3d<sub>5/2</sub> + 3d<sub>3/2</sub>) [34]. As it shows, since the energy separation between v and u terms is small, the Ce3d XPS spectrum is quite difficult to analyze.

**Figure 3.11.** Ce3d XPS region of CuO/CeO<sub>2</sub> catalyst in O<sub>2</sub> and CO-PROX reaction conditions at different temperatures. Dotted lines are the contribution of Ce<sup>3+</sup> species from the average deconvolution fitting [34].

In this regard, according to the type of assignation used, a gradual reduction of CeO<sub>2</sub> will result in the increase of v<sub>0</sub>, u<sub>0</sub> and v', u' structures with the expense of the decrease of the rest. Thus, the Ce<sup>3+</sup> content of the samples can be measured by the formula given by Equation 2.11, introduced in Chapter 2, as a simple percentual calculation for these contributions attributed to Ce<sup>3+</sup> species among the average [35]. Results of Ce<sup>3+</sup> estimation on the catalyst in the spectra under both source energies 1082 and 1372 eV, are presented altogether in Table 3.2, which shows that Ce<sup>3+</sup> content remains constant around 20% until 450 °C, where partial reduction of the CeO<sub>2</sub> occurs increasing Ce<sup>3+</sup> up to 33%. Comparing both source X-ray energies, it can be concluded that with the lower energy, it is possible to discern much better this partial reduction, which evidences the very high superficial degree of this reducing process since according to our IMFP

estimations, the target depth difference between both energies should not overcome 0.5 nm [33].

**Figure 3.12.** Cu2p XPS region of CuO/CeO<sub>2</sub> catalyst in O<sub>2</sub> and CO-PROX reaction conditions at different temperatures. **Caption:** Cu<sup>2+</sup> contribution (**dotted line**); Cu<sup>0</sup>+Cu<sup>+</sup>, or reduced Cu contribution (**solid line**).

Cu2p XPS spectra (Figure 3.12) show Cu2p<sub>3/2</sub> and Cu2p<sub>1/2</sub> peaks, as well as the well-reported shake-up satellite characteristic of Cu<sup>2+</sup> presence, which is used by some authors to provide qualitative fashion [36,37]. Since Cu2p<sub>3/2</sub> and Cu2p<sub>1/2</sub> peaks are well resolved in the Cu2p XPS spectrum, it is possible to analyze and focus on only the Cu2p<sub>3/2</sub> fraction, which enables much easier analysis when compared to Ce3d region. Thus, Cu2p<sub>3/2</sub> peak could be theoretically deconvoluted into three components, attributed to Cu<sup>0</sup>, Cu<sup>+</sup> and Cu<sup>2+</sup> contributions, respectively [38,39]. Unfortunately, the statistical separation of the Cu2p<sub>3/2</sub> peak positions for Cu<sup>0</sup> and Cu<sup>+</sup> is too little to discern between both reduced oxidation states, so it is convenient to perform a two-peak fitting using the precise constraints on BE, FWHM and peak-shape parameters, representative for (1) oxidized copper (CuO); and (2) undistinguishable reduced copper species (Cu and Cu<sub>2</sub>O).

It is worth to mention that for total resolution, the Cu L<sub>3</sub>M<sub>4.5</sub>M<sub>4.5</sub> Auger spectral line should be complementary analyzed and properly presented along with Cu2p<sub>3/2</sub> in the well-reported Wagner plots [40–42]. However, given the complex nature of the X-ray varying energy NAP-XPS experiments, this Auger line determination was not conducted, and Cu resolution was essentially done through Cu2p<sub>3/2</sub> fitting analysis. The semi-quantitative estimation of average oxidation state of surface copper species is presented in Table 3.2, showing that copper is gradually being reduced until achieving a total reduced state (Cu<sup>+</sup> and/or Cu<sup>0</sup>) at the highest temperature, whereas there is not much influence on the X-ray source energy. Interestingly, even in O<sub>2</sub> conditions during the oxidation pretreatment, there is a significative Cu<sup>I</sup> contribution which should be attributed to a promoted reducibility by the redox interplay between Ce and Cu ions.

It should be pointed out that while in CO-PROX conditions both 1082 and 1372 eV energies provide highly correlated results, in O<sub>2</sub>/N<sub>2</sub> mixture there are evident discrepancies, being Cu noticeably more reduced in the most external profile. Attending to this, the presence of that large reduced Cu content in CuO/CeO<sub>2</sub> catalyst in such oxidizing conditions is very questionable, given the well-known CuO facile oxidation. Consequently, it can be tentatively described that those differences are due to Cu – Ce synergistic interactions and labile Cu<sup>2+</sup>/Cu<sup>+</sup> equilibrium upon Ce<sup>4+</sup>/Ce<sup>3+</sup> redox exchange in the most external interfacial layers.

**Table 3.2.** Semi-quantitative determination from Ce3d, Cu2p XPS spectra and Cu L-edge XAS data from XANES analysis.

Conditions	XPS Ce <sup>3+</sup> (%)		XPS Cu <sup>2+</sup> (%)		Cu <sup>2+</sup> (%) XANES
	1082 eV	1372 eV	1082 eV	1372 eV	
O <sub>2</sub> /N <sub>2</sub> 200°C	20	22	66	75	88
CO-PROX 50°C	21	18	58	57	80
250°C	22	18	38	37	76
300°C	22	19	30	28	66
350°C	24	20	21	20	58
450°C	33	24	0	0	40

**Note:** Notice differences among XPS and XANES Cu<sup>II</sup> determination, attributed to the different environments: surface and bulk, respectively.

Cu L-edge XAS measurement of the CuO/CeO<sub>2</sub> catalyst was conducted in complement with NAP-XPS characterization during CO-PROX reaction. The recorded spectra are presented in Figure 3.13, and these exhibit the L<sub>3</sub> and L<sub>2</sub> pre-edge absorption peaks centered at ca. 930 and 950 eV, respectively, which correspond to the electric dipole allowed 2p → 3d transition [43,44].

**Figure 3.13.** Normalized and flattened Cu L-edge XANES spectra of CuO/CeO<sub>2</sub> catalyst in different conditions.

Hence, the resulting L-edge spectrum of the obtained CuO/CeO<sub>2</sub> catalyst is composed of proportional contributions of CuO, Cu<sub>2</sub>O and Cu characteristic spectral features. Namely, both CuO and Cu<sub>2</sub>O have well-resolved strong L<sub>3</sub> absorption edges, which were assigned with the peaks centered at 930.8 and 933.7 eV, respectively, in agreement with reported values [45,46]. On the contrary, Cu develops an unambiguous fingerprint that allows to identify traces of Cu among an average of mixed Cu<sub>x</sub>O species, although L<sub>3</sub> absorption edge would appear overlapped under the corresponding for Cu<sub>2</sub>O around 933.5 eV.

Thus, Near Edge XAS characterization provides a measure of the oxidation state of bulk copper particles present in the catalyst during CO-PROX reaction course. In this regard, the intensity ratios between the L<sub>3</sub> components with centers at *ca.* 930.7 and 933.7 eV is used herein as a qualitative indicator of the copper reduction degree and the results are presented in Table 3.2.

Considering that XAS is a bulk characterization analysis, in complement with XPS analysis, provides a combined description of the copper oxidation state along particle depth. Accordingly, as evidenced in

Table 3.2, Cu reduction is partial in the bulk, but total in surface of the Cu-rich particles.

Finally to correlate the XPS results with the CO-PROX catalytic activity,  $X_{CO}$  was estimated according to  $X_{O_2}$ , considering the disagreement between fixed-bed reactor experiments and operando NAP-XPS, and thus, CO selectivity along the temperature profile. Hence, Figure 3.14 gathers Ce<sup>III</sup> and reduced Cu species evolution determined by NAP-XPS and XANES for the CuO/CeO<sub>2</sub> catalyst plotted against  $X_{O_2}$ .

**Figure 3.14.** Distribution of surface Ce<sup>3+</sup> (**squares**) and reduced Cu species (**diamonds**) present in the CuO/CeO<sub>2</sub> catalyst during CO-PROX operando NAP-XPS experiment with the irradiation sources of 1082 eV (**solid symbols**); and 1372 eV (**open symbols**). XANES (bulk) Cu species distribution (**circles**).

In summary, gradual surface reduction of Cu species occurs along the CO-PROX reaction course, while only moderate and very superficial Ce reduction is observed for the CeO<sub>2</sub> support at the maximum  $X_{O_2}$ , that is with total  $X_{CO}$  and concomitant H<sub>2</sub> oxidation reaction. In agreement with previous studies, the presence of reduced copper is closely connected to H<sub>2</sub> oxidation reaction [4,8,47], as it fits with CO selectivity decay.

Since surface Cu<sup>I</sup> abundance is extraordinarily high at the beginning of the CO-PROX reaction, CuO should be partially reduced on surface upon CO contact, resulting in a very anticipated, but limited, CO oxidation activity. Rising the temperature leads to an enhancement of the reaction rate, which occurs via MVK mechanism by means of lattice-O abstraction and eventually provokes a gradual reduction of Cu<sub>x</sub>O particles, from the reactant area (surface) to the internal part of the particles (bulk). At the maximum measured temperature with total  $X_{O_2}$  and yet maximum  $X_{CO}$ , there is no trace of CuO on surface, and in this situation, the CuO particles present a (Cu<sup>0</sup>/Cu)

mixed reduced surface. It is reasonable to think that  $\text{Cu}^0$  component would constantly rise along with temperature increase, so that, overcoming certain reduction degree,  $\text{H}_2$  dissociation in Cu sites is more activated and  $\text{H}_2$  oxidation reaction is boosted, which additionally would create more reduced Cu sites.

In this scenario, it should be expected that  $X_{\text{CO}}$  would have decreased at higher temperatures at expenses of higher  $\text{H}_2$  oxidation rate by a larger extension on the Cu reduction. Additionally, we would have expected an increasing Cu bulk reduction degree. Unfortunately, we did not go so far at increasing the temperature in the NAP-XPS experiments given the difficulties to reach such high temperatures to overcome by large total  $X_{\text{O}_2}$  point.

On the contrary,  $\text{CeO}_2$  remains oxidized in an equilibrium state until surface CuO totally disappears. The disagreement between output from 1082 and 1372 eV energies suggests that Ce reduction is strictly limited to the most external surface, but likewise, would be expected to reach higher extension with higher temperatures as proven by *in situ* Raman experiments. Interestingly, considering that the synergistic Cu – Ce interactions should occur in the periphery of the intimate contacting  $\text{CeO}_2$  and  $\text{Cu}_x\text{O}$  particles, *i.e.* the finest surface, this result can be tentatively taken as an evidence of O transference from  $\text{CeO}_2$  to the partially reduced  $\text{Cu}_x\text{O}$  particles, acting as an oxygen supply to reconstitute active O.

Remarkably, this result allows to infer that CuO sites are important to keep a direct  $\text{O}_2$  uptake in the O vacancy generation – restitution equilibrium. Since O vacancy generation gains importance with the reaction course, the equilibrium is uncompensated and eventually CuO disappears. In this situation, given the scarcity of active O in the Cu-rich phase,  $\text{CeO}_2$  transfers lattice O in the Cu – Ce interfacial points, trying to compensate and prevent total reduction to metal Cu. Consequently,  $\text{O}_2$  recovery is meant to occur directly from  $\text{O}_2$  gas to the CuO particles, but not in the highly reduced  $\text{Cu}_x\text{O}$  sites, composed mainly of Cu and  $\text{Cu}_2\text{O}$  species. When such reduction degree is achieved,  $\text{CeO}_2$  should assist into the lattice O regeneration providing mobile O through the Cu – Ce interface.

In summary, according to the main results presented so far, the  $\text{CeO}_2$  support exhibits essentially two important roles: (1) intrinsically stabilizes  $\text{Cu}^{\text{I}}$  sites in the interfacial points, and thus, enables enhanced and anticipated CO oxidation activity; and (2) aids into  $\text{O}_2$  uptake once  $\text{Cu}_x\text{O}$  particles present a reduced state and CuO is no longer on surface to proceed with lattice-O recovery.

### 3.3.5 Density Functional Theory (DFT) Calculations

As a final remark to be included in this study, DFT calculations were conducted for the modelling of  $\text{CeO}_2(111)$ ,  $\text{CuO}(111)$  and  $\text{Cu}_2\text{O}(111)$

ssurface slabs, representative for the most abundant facets present in the CuO/CeO<sub>2</sub> catalyst. Figures 3.15a-c show the optimized structures:

**Figure 3.15.** (a) CeO<sub>2</sub>(111) surface slab with 12 Ce (yellow) and 24 O (red) ions; (b) CuO(111) surface slab with 64 Cu (brown) and 64 O ions; (c) Cu<sub>2</sub>O(111) surface slab, 64 Cu and 32 O ions. **Note:** (X) stands for fixed bulk positions.

Although it is well-known the heterogeneous and imperfect nature of this material, the modelling of the most common surfaces present individually can be taken as a reliable indicative of the properties of each active sites. On each surface slab, a surface oxygen vacancy was created and the slab left

afterwards was optimized searching for the most favorable electronic and ionic configurations. Thus, Table 3.3 collides the lowest energies found for the formation of an O-vacancy on these slabs, showing the trend as follows:  $\text{CuO}(111) > \text{CeO}_2(111) > \text{Cu}_2\text{O}(111)$ .

**Table 3.3.** Energies for the O vacancy formation in (111) surface slabs of  $\text{CeO}_2$ ,  $\text{CuO}$ , and  $\text{Cu}_2\text{O}$  crystal structures.

	$\text{CeO}_2(111)$	$\text{CuO}(111)$	$\text{Cu}_2\text{O}(111)$
O-vacancy formation energy (eV)	2.22	2.40	1.97

These energies are in agreement with the previously reported values, although they are highly dependent on the localization of the two extra electrons left upon O abstraction [48–50]. On the other hand, it is evident that the higher the energy for the oxygen vacancy formation, the more facile lattice oxygen restitution when the O-deficient slabs are set in contact with  $\text{O}_2$  atmosphere. Therefore, attending to the observed trend it is concluded that O-lattice recovery should prevail in  $\text{CuO}$ , when present, with regards to  $\text{CeO}_2$ , while once  $\text{CuO}$  is reduced to  $\text{Cu}_2\text{O}$  as CO-PROX reaction is taking place, the reoxidation through  $\text{CeO}_2$  is more favorable.

Hence, in agreement with the experimental approach, the theoretical study corroborates the proposed mechanism for the reoxidation of the  $\text{CuO}/\text{CeO}_2$  catalyst during CO-PROX reaction course, *i.e.* the O-lattice compensation with incoming  $\text{O}_2$  molecules. As a summary, Figure 3.16 presented below shows a graphical abstract of the ongoing processes.

**Figure 3.16.** Graphical scheme of the molecular processes occurring in the  $\text{CuO}/\text{CeO}_2$  catalyst in CO-PROX reaction. **Caption:** (□) stands for O vacancy.

### 3.4 Conclusions

Along the present Chapter, relevant data regarding the CO-PROX reaction mechanism study with CuO/CeO<sub>2</sub> catalyst has been discussed. The main insights and key points aborded are summarized in the following:

- (1) The simple preparation of conventional CuO/CeO<sub>2</sub> catalyst through nitrate calcination and impregnation results in an excellent performance in terms of CO conversion and CO selectivity in CO-PROX reaction.
- (2) The promoted Cu and Ce reducibilities by means of the synergistic Cu – Ce redox interactions, result in labile electronic exchanges between CuO and CeO<sub>2</sub> phases that activate surface oxygen from the lattice towards the MVK-based catalytic oxidation processes.
- (3) The labile Cu<sup>2+</sup>/Cu<sup>+</sup> – Ce<sup>3+</sup>/Ce<sup>4+</sup> redox interplay allows a great reversibility in the reduction – oxidation balanced processes occurring, and thus, confer to the CuO/CeO<sub>2</sub> catalyst a large stability and cyclability.
- (4) The CO oxidation activity is claimed to occur on Cu<sup>+</sup> surface states in the surface of CuO particles, whose formation is favored in the active Ce – Cu interface, whereas H<sub>2</sub> oxidation is activated when Cu<sup>0</sup> sites are present at higher reduction degrees.
- (5) In the CuO/CeO<sub>2</sub> catalyst, the role of CeO<sub>2</sub> is to promote the formation and stabilization of Cu<sup>I</sup> species, which leads to a great activity and a positive broad CO selective regime in CO-PROX reaction.
- (6) During CO-PROX process, oxygen vacancies are being created in the CuO<sub>x</sub> particles, claimed main active sites, and it is predicted that the catalyst reoxidation occurs directly on these particles via CuO-related sites.
- (7) When surface CuO species are not present because of extensive reduction in an advanced CO-PROX reaction degree, CeO<sub>2</sub> assists in the O<sub>2</sub> uptake since it is able to transfer highly mobile lattice O through the Ce – Cu interface to the Cu<sub>x</sub>O particles palliating massive copper reduction.

# CHAPTER 4

## Role of hydroxyl groups in CO-PROX reaction over CuO/CeO<sub>2</sub> catalysts

Chapter 4 presents a thorough Diffuse Reflectance Infra-red Fourier Transformed (DRIFT) spectroscopic study on CO-PROX reaction with model CuO/Ce<sub>0.8</sub>X<sub>0.2</sub>O<sub>δ</sub> catalysts (with X = Ce, Zr, La, Pr, or Nd). These have been fully characterized exhibiting different chemical features that correlate with catalytic activity. The CO oxidation rate over CuO/CeO<sub>2</sub> catalysts correlates with the formation of the Cu<sup>+</sup>-CO carbonyl above a critical temperature (90 °C for the experimental conditions in this study) because copper-carbonyl formation is the rate-limiting step. Above this temperature, CO oxidation capacity depends on the redox properties of the catalyst. However, decomposition of adsorbed intermediates is the slowest step below this threshold temperature. The hydroxyl groups on the catalyst surface play a key role in determining the nature of the carbon-based intermediates formed upon CO chemisorption and oxidation. Hydroxyls favor the formation of bicarbonates with respect to carbonates, and catalysts forming more bicarbonates produce faster CO oxidation rates than those which favour carbonates.

Davó-Quiñonero et al., *ACS Catalysis*, **6**(3) (2016) 1723-1731

## 4.1 Introduction

Chapter 3 has presented experimental and theoretical evidences that corroborate the excellent performance of CuO/CeO<sub>2</sub> catalysts towards the Preferential Oxidation of CO (CO-PROX) reaction. Attempts to improve this catalytic activity are not trivial as the range of improvement is very little provided the outstanding primary features from the bare CuO/CeO<sub>2</sub> conventional catalyst. With this aim, the doping of CeO<sub>2</sub> lattice with different elements such as Zr, Sm, Pr or La is, apparently, an interesting approach provided the inherent positive doping-effect into oxygen storage capacity, redox properties or crystalline size of the support. Nevertheless, widely reported studies show how ceria doping results in detrimental towards the catalytic activity of CuO/Ce<sub>1- $\delta$</sub> X <sub>$\delta$</sub> O<sub>2</sub> catalysts for every  $\delta$  varying content. The general explanation accepted for this negative effect are attributed to the loss of synergistic redox interactions existing among Cu<sup>2+</sup>/Cu<sup>+</sup> – Ce<sup>+4</sup>/Ce<sup>+3</sup> pairs as doping cations block the necessary interfacial contact and hinder the redox interplay for the formation and stabilization of Cu<sup>+</sup> states.

However, solid evidences that reinforce these arguments are not abundant given the complex nature of the synergistic Cu – Ce interactions and, in addition, very little has been addressed the ceria-doping effect into the surface chemistry evolution during CO-PROX reaction. In this scenario, in this Chapter a series of CuO/Ce<sub>0.8</sub>X<sub>0.2</sub>O <sub>$\delta$</sub>  catalysts (with X = Ce, Zr, La, Pr, or Nd) has been prepared in order to obtain materials with different chemical features, and these have been tested on CO-PROX *operando* DRIFT spectroscopy. The objectives were to understand the role of the carbon-containing intermediates in the CO oxidation reaction, to determine whether the hydroxyl groups on the catalyst influence the formation of bicarbonates in preference to carbonates, and to provide evidence to support a hypothesis that catalysts which preferentially form bicarbonates are able to oxidize CO faster than those forming carbonate-type species.

## 4.2 Experimental section

### 4.2.1 Catalysts preparation

Five metal oxides with composition Ce<sub>0.8</sub>X<sub>0.2</sub>O <sub>$\delta$</sub>  (X = Ce, Zr, La, Pr or Nd) were prepared by decomposition of the corresponding metal nitrates aqueous dissolution dissolved in the proper amounts, using “flash” calcination protocol, as described in [Section 2.2.1](#) from Chapter 2. CuO/Ce<sub>0.8</sub>X<sub>0.2</sub>O <sub>$\delta$</sub>  catalysts (5 wt. % Cu) were prepared by impregnation followed by flash calcination in the same protocol as for the support preparation.

#### 4.2.2 Catalysts characterization

Samples were characterized by means of X-Ray Diffraction (XRD) for the calculation of average crystallite size of the mixed oxide supports by means of Williamson-Hall's equation. The specific surface areas, pore volumes and pore sizes were determined from N<sub>2</sub> physisorption analysis. Raman spectra were recorded with Nd-YAG laser source (1064 nm), instead of He-Ne as in the rest of the Thesis, in attempts to avoid fluorescence effect from certain dopants. The catalysts reducibility was measured by means of temperature programmed reduction with H<sub>2</sub> (H<sub>2</sub>-TPR) experiments, as described in [Section 2.2.2](#) from Chapter 2.

#### 4.2.3 CO-PROX activity tests

The prepared CuO/Ce<sub>0.8</sub>X<sub>0.2</sub>O<sub>δ</sub> catalyst series was tested in CO-PROX catalytic tests according to the experimental settings and specific conditions as stated in [Section 2.2.3](#). Briefly, 100 ml/min of the CO-PROX gas mixture consisting in 2% CO, 2% O<sub>2</sub>, 30% H<sub>2</sub> in He balance ( $\lambda = 2$ ) was fed to the reactor with 150 mg of sample, and the experiment was conducted following heating rate of 2°C/min from 25 to 250°C.

#### 4.2.4 Operando DRIFTS-MS experiments.

The reaction mechanism was studied by means of Diffuse Reflectance Infra-red Fourier Transform spectroscopy (DRIFTS), performed in CO-PROX reaction conditions (*operando*) coupled to MS. The reaction gas mixture was set in 50 ml/min of 2% CO, 2% O<sub>2</sub>, 58% H<sub>2</sub> balanced with He; passing through the pre-treated catalyst bed (100 mg), and the temperature was raised at 5°C/min while infrared spectra were recorded at 10°C intervals. Further details on the specific settings are provided in [Section 2.2.4.1](#) from Chapter 2.

### 4.3 Results

#### 4.3.1 Textural and crystalline catalysts characterization

The crystalline structure and porosity of the catalysts was characterized by XRD, N<sub>2</sub> adsorption, and Raman spectroscopy. The X-ray diffractograms are compiled in Figure 4.1 and the crystallite sizes and cell parameters calculated for the ceria-based supports are compiled in Table 4.1.

**Figure 4.1.** X-Ray diffractograms of the catalysts.

All diffractograms show the typical reflexions of the fluorite structure of ceria, and also tiny peaks of CuO at 35.7 and 39.0° seem to be present in most catalyst. Evidence of other crystalline phase are only identified for the CuO/Ce<sub>0.8</sub>Zr<sub>0.2</sub>O<sub>δ</sub> catalyst, which shows a shoulder at the right-hand side of the (111) fluorite peak at 29.0° that is consistent with the presence of a Zr-rich tetragonal phase (peak 111). Evidence of segregated phases of La, Pr or Nd was not observed in the diffractograms.

**Table 4.1.** Results of the catalysts characterization by N<sub>2</sub> adsorption, XRD and Raman spectroscopy.

Catalyst	S <sub>BET</sub> (m <sup>2</sup> /g)	V <sub>DR</sub> (cm <sup>3</sup> /g)	PSD BJH (nm)	Crystal size (nm)	Lattice constant (nm)	F <sub>2g</sub> Raman shift (cm <sup>-1</sup> )
CuO/CeO <sub>2</sub>	58	0.021	12	13	0.5407	441
CuO/Ce <sub>0.8</sub> Zr <sub>0.2</sub> O <sub>δ</sub>	60	0.020	12	13	0.5392	457
CuO/Ce <sub>0.8</sub> La <sub>0.2</sub> O <sub>δ</sub>	40	0.015	17	26	0.5448	446
CuO/Ce <sub>0.8</sub> Pr <sub>0.2</sub> O <sub>δ</sub>	35	0.013	12	27	0.5411	450
CuO/Ce <sub>0.8</sub> Nd <sub>0.2</sub> O <sub>δ</sub>	45	0.016	12	16	0.5429	453

The cell parameter calculated for the ceria bare support (0.5407 nm) is consistent with values typically obtained for this material [3], and doping with some cations affect this value. The cell parameter does not change significantly upon ceria doping with Pr, which is not surprising because the sizes of the Ce cations (0.097 nm for Ce<sup>4+</sup> and 0.114 nm for Ce<sup>3+</sup>) are almost equal to those of Pr cations (0.096 nm for Pr<sup>4+</sup> and 0.113 nm for Pr<sup>3+</sup>) [4]. On

the contrary, Zr doping decreases the cell parameter of ceria while doping with La or Nd increases the cell parameter. The cell parameter contraction upon Zr doping is expected considering the smaller size of Zr<sup>4+</sup> (0.084 nm) with regard to Ce<sup>4+</sup>, and the cell expansion upon La or Nd doping is consistent with the bigger size of their cations (0.116 nm for La<sup>3+</sup> and 0.112 nm for Nd<sup>3+</sup>). These modifications of the cell parameters of ceria upon doping provide evidence that the foreign cations are actually located into the parent ceria framework. However, it cannot be ruled out that, in addition to the amount introduced into the ceria lattice, Zr is partially segregated, since evidence of such segregated phase is observed in the diffractograms, as mentioned.

The pore size (12-17 nm) and pore volume (0.013-0.021 cm<sup>3</sup>/g) values are quite similar for all catalysts. The crystallite sizes of the ceria supports are in the 13-27 nm range (see Table 4.1), and the smallest sizes are obtained for undoped and Zr-doped ceria. These two supports also have the largest specific surface areas (58-60 m<sup>2</sup>/g), these values being in good agreement with those typically obtained for cerium oxides exposed to a similar thermal history [3]. Ceria doping with La, Pr or Nd leads to a decrease of the specific surface area and an increase of the crystallite size, which means that these dopants induce sintering. It is known that the effect of dopants on ceria sintering depends on the temperature of the thermal treatments [5]. As a rule of thumb, dopants partially hinder ceria sintering for high temperature calcination (above 800-900°C) while they have no effect or promote sintering for mild temperature calcination (500-600°C). The argument postulated to explain such behavior is that the surface defects created upon doping decrease the energy required for crystals to merge, and therefore dopants promote sintering if there are energy restrictions, as occurring at mild temperature. On the contrary, if the temperature is high enough to overcome such energy restrictions to sintering, the effect of dopants is the opposite, partially hindering sintering because they do not allow long-range structural order into the ceria crystals.

Raman spectroscopy (Figure 4.2) provides additional information about the structure of the catalysts. All catalysts show the F<sub>2g</sub> band around 450 cm<sup>-1</sup>, typical feature of the ceria-based oxides [6,7]. This band has been attributed to the oxygen breathing frequency around the Ce<sup>4+</sup> cations [8,9]. The position of this band provides information about the introduction of foreign cations into the ceria lattice. The position of the F<sub>2g</sub> band in pure ceria is usually ca 464 cm<sup>-1</sup> [3], and the position obtained for all CuO/Ce<sub>0.8</sub>X<sub>0.2</sub>O<sub>δ</sub> catalysts is well below this value (see data in Table 4.1). The shift of the F<sub>2g</sub> band towards low values is attributed to the presence of foreign cations into the lattice larger than Ce<sup>4+</sup>, while the shift towards high values is assigned to the presence of smaller cations. Therefore, the low values obtained for our catalysts suggest the presence of large cations. In the CuO/CeO<sub>2</sub> catalyst, the large cations could be Ce<sup>3+</sup> and a potential explanation would be that the energy of the laser used to obtain the Raman spectra is sufficiently high to

partially reduce the surface. Copper seems to play a key role in this reduction, because this effect is not observed in copper-free ceria catalysts [19]. In catalysts with dopants larger than  $\text{Ce}^{4+}$ , like  $\text{La}^{3+}$ ,  $\text{Pr}^{3+}$  and  $\text{Nd}^{3+}$ , the shift of the  $\text{F}_{2g}$  band below  $464\text{ cm}^{-1}$  must be additionally attributed to the introduction of such cations into the ceria lattice. It is also reasonable to think that  $\text{Ce}^{4+}$  reduction (and also  $\text{Pr}^{4+}$  in the case of  $\text{CuO/Ce}_{0.8}\text{Pr}_{0.2}\text{O}_\delta$ ) is additionally taking place.

**Figure 4.2.** Raman spectra of the catalysts. The spectra were normalized by dividing the intensity of each spectrum between the intensity of its  $\text{F}_{2g}$  band maximum.

In addition to the  $\text{F}_{2g}$  band, another band or shoulder appears in some Raman spectra at  $540\text{ cm}^{-1}$ , which has been assigned to oxygen vacancies. The relative intensity of this band with regard to the maximum of the  $\text{F}_{2g}$  band is highest for the Pr-containing catalyst, being much lower for the La- or Nd-doped catalysts and negligible for the remaining samples. The formation of oxygen vacancies is expected upon  $\text{Ce}^{4+}$  substitution by trivalent cations, like  $\text{La}^{3+}$  or  $\text{Nd}^{3+}$ , while is not expected to be relevant upon isovalent substitution of  $\text{Ce}^{4+}$  by  $\text{Zr}^{4+}$ . The prominent vacancies band observed in  $\text{CuO/Ce}_{0.8}\text{Pr}_{0.2}\text{O}_\delta$  has been attributed to the easy reduction of the  $\text{Pr}^{4+}$  cations, which could be even reduced due to the local heating produced by the laser used to excite the samples and obtain the Raman spectra, as previously reported.<sup>20</sup> The

presence of Ce<sup>3+</sup> cations, as previously proposed considering the position of the F<sub>2g</sub> band, is also expected to lead to the formation of oxygen vacancies. However, the band due to these vacancies is negligible in spectra of CuO/CeO<sub>2</sub>, for instance, suggesting that the partial reduction of Ce<sup>4+</sup> under measurements conditions is high enough to shift the position of the F<sub>2g</sub> band but not for the band due to the vacancies to grow. This is not surprising because, usually, the position of the Raman bands is much more sensitive to changes in the physical chemical features of solids than the intensity of the bands, which is affected by other variables like crystal size or radiation absorption.

In conclusion, these characterization results confirm that, in the CuO/Ce<sub>0.8</sub>X<sub>0.2</sub>O<sub>δ</sub> catalysts prepared, the doping cations are actually located into the parent ceria framework. Only the CuO/Ce<sub>0.8</sub>X<sub>0.2</sub>O<sub>δ</sub> catalyst shows certain evidences of the formation of a segregated Zr-rich phase, but even in this case, it can be confirmed that part of the Zr dopant is located into the ceria lattice.

#### 4.3.2 Catalysts characterization by H<sub>2</sub>-TPR.

The TCD signals monitored during the H<sub>2</sub>-TPR experiments are plotted on Figure 4.3, and all catalysts show a main feature in the 120-300°C range, which consist of double peaks or a main peak with a shoulder at low temperature. Also, a small band is shown in some profiles around 800°C, which can be assigned to the reduction of the particles bulk.

The position of the low-temperature reduction bands indicates that CuO/Ce<sub>0.8</sub>Zr<sub>0.2</sub>O<sub>δ</sub> and CuO/CeO<sub>2</sub> are reduced at the lowest temperature, and that the behavior of these two catalysts is quite similar to each other. Different events are taking place within the reduction bands in the 120-300°C range, and the dual-mode shape reported for MO/CeO<sub>2</sub> catalysts (MO = Metal Oxide) has been related to the reduction of the supported metal oxide (MO) and ceria in close contact with MO at the lowest temperature, and to surface ceria reduction which is not directly in contact with MO at higher temperature [10]. In the case of CuO catalysts, the reduction of Cu<sup>2+</sup> to Cu<sup>0</sup> in two consecutive steps, Cu<sup>2+</sup> to Cu<sup>+</sup> first and Cu<sup>+</sup> to Cu<sup>0</sup> afterwards cannot be ruled out. In the CuO/Ce<sub>0.8</sub>Pr<sub>0.2</sub>O<sub>δ</sub> catalyst it must be additionally taken into account that Pr<sup>4+</sup> is also reduced to Pr<sup>3+</sup>. Quantitative values calculated from the H<sub>2</sub>-TPR experiments are compiled in Table 4.2:

**Figure 4.3.** H<sub>2</sub>-TPR profiles of the catalysts.

**Table 4.2.** Quantitative values calculated from the H<sub>2</sub>-TPR experiments. <sup>a</sup>In the CuO/Ce<sub>0.8</sub>Pr<sub>0.2</sub>O<sub>δ</sub> catalyst, the percentage of Ce<sup>4+</sup> reduced is actually Ce<sup>4+</sup> + Pr<sup>4+</sup>.

Catalyst	H <sub>2</sub> consumed mol/CuO mol	Ce <sup>4+</sup> reduced (%)
CuO/CeO <sub>2</sub>	1.7	20
CuO/Ce <sub>0.8</sub> Zr <sub>0.2</sub> O <sub>δ</sub>	1.6	22
CuO/Ce <sub>0.8</sub> La <sub>0.2</sub> O <sub>δ</sub>	1.6	23
CuO/Ce <sub>0.8</sub> Pr <sub>0.2</sub> O <sub>δ</sub>	1.9	27 <sup>a</sup>
CuO/Ce <sub>0.8</sub> Nd <sub>0.2</sub> O <sub>δ</sub>	1.8	28

In all cases, the moles of H<sub>2</sub> consumed are higher than those of CuO on the catalysts, and this provides experimental evidence that not only is CuO being reduced but also the ceria supports. Considering total reduction of Cu<sup>2+</sup> to Cu<sup>0</sup>, the percentages of Ce<sup>4+</sup> reduced to Ce<sup>3+</sup> are in the 20-28 % range for all catalysts.

These H<sub>2</sub>-TPR experiments allow concluding that the presence of dopants affect the reducibility of the CuO-Ceria system, and

CuO/Ce<sub>0.8</sub>Zr<sub>0.2</sub>O<sub>δ</sub> and CuO/CeO<sub>2</sub> are reduced more easily than the remaining catalysts. This affects the temperature required for catalysts reduction by H<sub>2</sub>, but differences in the extent of the reduction are not very relevant once totally accomplished.

#### 4.3.3 Catalytic tests in a fixed-bed reactor

Figure 4.4 shows the oxidation of CO (Figure 4.4a) and the CO selectivity (Figure 4b) obtained in the fixed-bed reactor PROX experiments, where it is observed that the catalysts with the undoped and Zr-doped supports are active and selective at lower temperature than catalysts containing La, Pr or Nd.

**Figure 4.4.** CO-PROX reactions performed in a fixed-bed reactor. **(a)** CO conversion (X<sub>co</sub>) and **(b)** CO selectivity (Sel.)

The results on Figure 4.4, together with the previous H<sub>2</sub>-TPR characterization, confirm that the reducibility of the catalyst plays an important role in CO oxidation, since the catalytic processes are based on

redox cycles taking place on the catalyst surface. In accordance with the well accepted role of the different copper species in the PROX reactions [11,12], the oxidation of CO starts at temperatures ( $\sim 50^{\circ}\text{C}$ ) lower than those required for the massive reduction of the catalyst by  $\text{H}_2$  (see  $\text{H}_2$ -TPR in Figure 4.3). This is in agreement with the hypothesis supporting that the active sites for CO oxidation are  $\text{Cu}^+$  sites located at the CuO-Ceria interface. In addition, the selectivity drops (Figure 4.4b) when temperature approaches the onset temperature for massive reduction of the catalysts (see  $\text{H}_2$ -TPR in Figure 4.3), supporting that  $\text{H}_2$  oxidation takes place on reduced metal sites.

#### 4.3.4 *Operando* DRIFTS-MS experiments.

In order to investigate the nature of the carbon intermediates and to demonstrate that the catalyst hydroxyl groups play a critical role in the formation of bicarbonates and in the CO oxidation rate, which is the main goal of the study, *operando* DRIFTS-MS experiments were carried out.

Figure 4.5 shows, as representative examples, spectra obtained with  $\text{CuO/Ce}_{0.8}\text{Zr}_{0.2}\text{O}_8$  and  $\text{CuO/Ce}_{0.8}\text{La}_{0.2}\text{O}_8$ . DRIFT spectra were recorded between  $4000\text{-}1000\text{ cm}^{-1}$ , but the main features are located in three main regions. Figures 4.5a and 4.5d show the  $1650\text{-}1150\text{ cm}^{-1}$  range, where several vibration/stretching modes corresponding to carbonates, bicarbonates and formates are identified. Figures 4.5b and 5e show the  $2250\text{-}1950\text{ cm}^{-1}$  range, where a single band corresponding to the  $\text{Cu}^+\text{-CO}$  carbonyl is observed. Figures 4.5c and 4.5d show the  $3850\text{-}2450\text{ cm}^{-1}$  range, where hydroxyl groups show their main features.

**Figure 4.5.** DRIFT spectra obtained as a function of temperature under operando PROX conditions with **(a,b,c)** CuO/Ce<sub>0.8</sub>Zr<sub>0.2</sub>O<sub>δ</sub> and **(d,e,f)** CuO/Ce<sub>0.8</sub>La<sub>0.2</sub>O<sub>δ</sub>.

#### 4.3.4.1 Role of the catalyst hydroxyls groups

The main carbon-containing reaction intermediates accumulated on the catalysts surface during the PROX reaction are carbonates and bicarbonates, as is observed in the DRIFT spectra of Figure 4.5. Figure 4.6 shows the ratio between the band maxima due to bicarbonates (at 1395 cm<sup>-1</sup>) and carbonates (at 1460 cm<sup>-1</sup>) bands as a function of temperature for all catalysts.

**Figure 4.6.** Ratio between the absorbance at 1395  $\text{cm}^{-1}$  (bicarbonates) and the absorbance at 1460  $\text{cm}^{-1}$  (carbonates) as a function of temperature.

The most active catalysts ( $\text{CuO/CeO}_2$  and  $\text{CuO/Ce}_{0.8}\text{Zr}_{0.2}\text{O}_x$ ) favor the formation of surface bicarbonates in preference of carbonates, while catalysts with lower CO-PROX activity ( $X = \text{La, Pr or Nd}$ ) accumulate more carbonates on the surface. The positive effect on the CO oxidation rate of surface bicarbonates formation as reaction intermediates with regards to carbonates could be related to the lower thermal stability of the former species, which would lead to a faster desorption of  $\text{CO}_2$  leaving the surface available for further chemisorbing other reaction intermediates more rapidly. This would suggest that, in some circumstances, the slow step of the reaction mechanism is the surface intermediates desorption, and this hypothesis is discussed afterwards in more detail.

Catalysts hydroxyls are involved in the formation of surface bicarbonates, as it is deduced from Figure 4.7 where the intensity of the bicarbonates band at 1395  $\text{cm}^{-1}$  is plotted as a function of the area of the hydroxyls band (3600-2500  $\text{cm}^{-1}$  range). Note that the area of the hydroxyls band shows negative values because hydroxyls are consumed during the reactions. Linear relationships between the consumption of hydroxyls and the formation of bicarbonates are observed for all catalysts suggesting that the two processes are related to each other.

**Figure 4.7.** Relationship between bicarbonates formation (band at 1395 cm<sup>-1</sup>) and hydroxyls consumption (band in the 2500-3600 cm<sup>-1</sup> range).

Figure 4.7 also shows that the linear trend is valid for the whole range of temperatures studied (25-200 °C) for the most active catalysts (CuO/CeO<sub>2</sub> and CuO/Ce<sub>0.8</sub>Zr<sub>0.2</sub>O<sub>8</sub>) but not for those with lower activity (X= La, Pr or Nd). Catalysts with X= La, Pr or Nd show a deviation from the trend line of Figure 4.7 above a certain temperature, and according to results of Figure 4.4b, this deviation occurs at a stage where the CO selectivity decreases, that is, where the onset of H<sub>2</sub> oxidation begin. A vertical drop in Figure 4.7 indicates that the amount of surface hydroxyls remains constant above a certain temperature while surface bicarbonates are depleted, that is, once the oxidation of H<sub>2</sub> is initiated the formation of carbonate-like intermediates is favored with respect to bicarbonates.

According to these results and the background literature, our proposed CO oxidation mechanism is as follows:

where CuO are active sites for CO chemisorption at the copper oxide-cerium oxide interface, Cu<sub>2</sub>O-O-CO represents the Cu<sup>+</sup>-CO carbonyl, <sup>\*</sup>-O are chemisorption sites where surface carbonates (<sup>\*</sup>-CO<sub>3</sub>) are formed and <sup>\*</sup>-OH are chemisorption sites where surface bicarbonates (<sup>\*</sup>-CO<sub>2</sub>OH) are formed.

The CO oxidation reaction mechanism starts with CO chemisorption at the copper oxide-cerium oxide interface and formation  $\text{Cu}^+\text{-CO}$  carbonyls (step 1), and it has been proposed that chemisorbed CO is oxidized to  $\text{CO}_2$  following a Mars van Krevelen mechanism using the  $\text{Cu}^{2+}/\text{Cu}^+$  redox cycle [13]. Then,  $\text{CO}_2$  is transferred from the copper oxide-cerium oxide interface to other surface sites, probably on the ceria support, forming bicarbonates (step 2a) and carbonates (step 2b), and molecular oxygen reoxidizes the reduced sites via steps 3. Surface hydroxyls are involved in the formation of bicarbonates (step 2b). Finally,  $\text{CO}_2$  is desorbed following steps 4a and 4b.

#### 4.3.4.2 *Products poisoning versus $\text{Cu}^+\text{-CO}$ carbonyl*

The contribution to the CO oxidation rate of the copper oxide-cerium oxide interface reducibility and of the carbon products desorption has been analyzed.

Figure 4.8 shows the area of the  $\text{Cu}^+\text{-CO}$  carbonyl peak monitored under CO-PROX reaction conditions for all  $\text{CuO}/\text{Ce}_{0.8}\text{X}_{0.2}\text{O}_\delta$  catalysts as a function of the reaction temperature, where it is observed that the room temperature formation of the  $\text{Cu}^+\text{-CO}$  carbonyl obtained with the Zr-containing catalyst is about three times higher to that formed on the undoped  $\text{CuO}/\text{CeO}_2$  counterpart, and that the  $\text{Cu}^+\text{-CO}$  carbonyl formation is delayed to higher temperatures for catalysts with  $\text{X} = \text{La}$ ,  $\text{Pr}$  or  $\text{Nd}$ .

**Figure 4.8.** Integrated area of the  $\text{Cu}^+\text{-CO}$  carbonyl band at  $2100\text{ cm}^{-1}$  as a function of the reaction temperature.

The temperature of maximum carbonyl coverage has been determined from Figure 4.8, and these temperatures correlate to the CO oxidation rates. Figure 4.9 shows the relationship between the CO oxidation rate and the formation of the  $\text{Cu}^+\text{-CO}$  carbonyl in the CO-PROX experiments. The data for most  $\text{CuO}/\text{Ce}_{0.8}\text{X}_{0.2}\text{O}_\delta$  catalysts lie on a straight line, confirming the important role of the reducibility of the copper oxide-cerium oxide interface.<sup>15</sup>

**Figure 4.9.** Relationship between CO oxidation rate and temperature corresponding to the maximum absorbance due to Cu<sup>+</sup>-CO carbonyl.

However, the CO oxidation rate obtained with the Zr-containing catalyst is lower than that predicted by its Cu<sup>+</sup>-CO carbonyl population. These results indicate that the Cu<sup>+</sup>-CO carbonyl formation (step 1) is the rate limiting step for temperatures above a certain threshold (above 90 °C approximately for the experimental conditions of this study) but, below this temperature, the accumulation of reaction products on the catalyst surface must also be taken into account because desorption of reaction intermediates (steps 4a and 4b) becomes the slowest step of the mechanism.

The area of a broad DRIFTS band envelope with several contributions appearing in the 1650-1300 cm<sup>-1</sup> range has been calculated. This band can be attributed to surface carbonates and bicarbonates (and formates, in particular cases). Figure 4.10 shows the area of this band as a function of the reaction temperature for all catalysts.

**Figure 4.10.** Integrated area of the band due to carbon containing products (carbonates + bicarbonates + formates) in the 1650-1300 cm<sup>-1</sup> range as a function of the reaction temperature.

The accumulation of carbon containing reaction products is highest for the Zr-containing catalyst, its area of the 1650-1300  $\text{cm}^{-1}$  band being, for instance, twice that of  $\text{CuO/CeO}_2$  at 50 °C. The poisoning by the formation of carbon containing adsorbed intermediates explains why the CO oxidation rate of the  $\text{CuO/Ce}_{0.8}\text{Zr}_{0.2}\text{O}_8$  catalyst does not follow the trend predicted by the formation of the  $\text{Cu}^+\text{-CO}$  carbonyl (Figure 4.9). Comparison of the  $\text{CuO/CeO}_2$  and  $\text{CuO/Ce}_{0.8}\text{Zr}_{0.2}\text{O}_8$  behavior is interesting because both catalysts show similar CO-PROX activity, the latter more readily forming the  $\text{Cu}^+\text{-CO}$  carbonyl at low temperature but also suffering much stronger inhibition by adsorbed products. Therefore, the contribution to the CO oxidation rate of the  $\text{Cu}^+\text{-CO}$  carbonyl formation and carbon products desorption oppose each other at low temperature. Taking the trend of Figure 4.9 into account, poisoning by reaction products becomes of special relevance at temperatures below ca. 90 °C for the experimental conditions used in this study.

The CO-PROX experiments performed in this study show that ceria doping with foreign cations has either no effect or a negative impact on the activity, and this observation has been also reported by many authors [10]. There have been only reported few examples of improved CO-PROX activity of copper oxide-ceria activity upon ceria doping [14–16], but the reasoning why some authors observe the positive effect of ceria doping while most do not has not been fully explained. It has been proposed that the incorporation of foreign cations into the ceria lattice hinders the extent of copper oxide-ceria interaction and it is this interface where the most active sites for CO oxidation are located [16,17]. Temperature programmed reduction experiments performed with  $\text{H}_2$ , (Figure 4.3), also indicate that the onset reduction temperature is lowest for the most active catalysts in the CO-PROX reaction ( $\text{CuO/CeO}_2$  and  $\text{CuO/Ce}_{0.8}\text{Zr}_{0.2}\text{O}_8$ ), that is, most dopants ( $X = \text{La, Pr or Nd}$ ) retard CO oxidation with regard to  $\text{CuO/CeO}_2$  and  $\text{CuO/Ce}_{0.8}\text{Zr}_{0.2}\text{O}_8$  because they delay the onset in the reduction temperature.

#### 4.3.4.3 Comparing CO-PROX with other catalytic reactions

The observed lack of influence or negative effect of ceria doping in the CO-PROX activity is in disagreement with the general behavior of ceria in most catalyzed reactions, such as in Three Way Catalysts (TWC) where ceria doping by  $\text{Zr}^{4+}$  enhances the oxygen storage capacity, the redox properties, and overall, the catalytic performance [18]. The positive effect of ceria doping has been also reported for ceria-catalyzed diesel soot combustion [19–21] or  $\text{NO}_x$  storage and Reduction (NSR) on Pt/Ceria catalysts [22], for instance, where the redox properties of ceria play an important role.

An important difference between the CO-PROX reaction and the other applications where the doping of ceria has a positive effect is the range of temperatures where the reactions take place. Ceria doping with foreign

cations usually has a positive effect on the activity for catalytic applications occurring at medium or high temperatures (around 200-300°C for TWC and NSR or > 400 °C for soot combustion, for instance). Dopants improve the thermal stability, oxygen storage capacity and/or some other physico-chemical properties of the ceria-based oxide, and therefore the catalytic activity, but the potential stabilization of the reaction intermediates on the catalyst has a minor effect on the reaction rate because the temperature is high enough to encourage desorption of the reaction products. On the other hand, the CO-PROX reaction takes place below ca 100°C, and desorption of reaction products becomes a critical step. Therefore, the challenge for CO-PROX is to prepare copper oxide-cerium oxide catalysts which are readily reducible at low temperature but that, at the same time, also desorb the reaction products at low temperature, and the participation of catalyst hydroxyls in the formation of bicarbonates as reaction intermediates has a positive effect.

#### 4.4 Conclusions

In summary, it can be concluded that the CO oxidation rate accelerated by copper oxide-cerium oxide catalysts in CO-PROX conditions correlates to the formation of the Cu<sup>+</sup>-CO carbonyl above a critical temperature (90°C for the experimental conditions of this study) because Step 1 (copper carbonyl formation) is the rate limiting one. However, desorption of carbon products (Steps 4a and 4b) is the slowest step below this threshold temperature. The hydroxyl groups on the catalyst surface play a key role in determining the nature of the carbon-based intermediates formed upon CO chemisorption and oxidation. Hydroxyls favor the formation of bicarbonates with respect to carbonates, and catalyst forming more bicarbonates reach faster CO oxidation rates than those which favor carbonates.

## CHAPTER 5

# CuO/Cryptomelane catalyst for preferential oxidation of CO in the presence of H<sub>2</sub>

Non-RE metal-based, Cryptomelane and CuO/Cryptomelane catalysts have been tested in CO-PROX reaction, paying special attention to deactivation and regeneration issues. Cryptomelane was stable during CO-PROX reactions in ramp experiments until 200°C and in a long-term isothermal experiment, exhibiting after use no changes neither in crystallinity nor H<sub>2</sub> reducibility. On the contrary, CuO/Cryptomelane, though being much more active, deactivated in consecutive CO-PROX reaction cycles performed until 200°C, but the catalytic activity was partially restored reoxidising the catalyst at 200°C or 400°C, the latter temperature being more effective. After four cycles of reaction, stable behavior was achieved, and then CuO/Cryptomelane demonstrated higher catalytic activity than that of Cryptomelane, even after its deactivation along cycles. Such deactivation has been attributed to potential causes: cryptomelane structure collapse into the crystallization of new phases (hausmannite (Mn<sub>3</sub>O<sub>4</sub>) and/or hopcalite (CuMn<sub>2</sub>O<sub>4</sub>)); segregation of potassium and decrease of the copper cations reducibility, whereas possible changes in the porous texture of CuO/Cryptomelane was ruled out.

## 5.1 Introduction

As stated and demonstrated in this Project Thesis, CuO/CeO<sub>2</sub> system, allows to provide excellent catalytic features while skipping the high expenses of noble metals and the lack of stability of Au-based catalysts, gaining big opportunities on their extended implementation into CO-PROX technologies [1,2]. The outstanding performance of the CuO/CeO<sub>2</sub> catalysts in CO-PROX is related to the strong interaction between CuO and CeO<sub>2</sub> and to the oxygen storing/releasing capacity of ceria, which leads to an important mobilization of active lattice oxygen [3,4]. Thus, in previous Chapters 3 and 4, the unique properties of the CuO/CeO<sub>2</sub> catalyst have been well described, besides a thorough study of the reaction mechanism and such oxygen activation process has been conducted. As it was proven, and/or elsewhere reported, apart from its excellent activity and selectivity to CO oxidation in the low temperature range of CO-PROX reaction conditions, CuO/CeO<sub>2</sub> systems possess great qualities such as certain CO<sub>2</sub> and H<sub>2</sub>O compatibility, or large stability in cyclability and long-time operation catalytic tests [5], for which CuO/CeO<sub>2</sub> and derived materials are ideal catalysts for this application.

However, the supply of cerium oxide is limited and subjected to geopolitical interests, since Rare Earths (RE) mineral sources are heterogeneously distributed over the planet and their extraction costs are very high not only economically but also environmentally [6]. In this regard, there is a deep, but not patent yet, problematic in RE metals use, which are nowadays present in nearly every electronic device and their demand is dramatically rising [7]. Therefore, the implementation of ceria-based catalytic technologies in CO-PROX reaction is only partially practicable since near-future strategies are meant to restrict RE use whenever efficient substitutes are available [8]. As a result, potential catalytic alternatives to cerium oxide materials are a need, and manganese oxides are claimed to be potential candidates for that purpose.

Manganese oxides are a very promising option to replace ceria due to their natural abundance, high oxygen mobility and oxygen storage capacity, apart from their low cost, environmental compatibility and non-toxicity [9,10]. The mineral oxide cryptomelane is based on a well-defined 2 x 2 tunnel structure (tunnel size of 0.46 nm x 0.46 nm) consisting of double chains of edge-shared MnO<sub>6</sub> octahedra and corner-sharing of the double chains [11,12], which gives rise to its general name “Octahedral Molecular Sieve” (OMS) [13]. Typically, the average manganese oxidation state in cryptomelane is around 3.8, which is a consequence of the coexistence of Mn<sup>4+</sup> cations with small amounts of Mn<sup>3+</sup> and Mn<sup>2+</sup> [14], and the charge imbalance generated by partial reduction of Mn<sup>4+</sup> is compensated by interstitial cations, such as K<sup>+</sup> and water species. Among manganese oxides, cryptomelane has presented an exceptional catalytic activity in a wide range of reactions [15–22],

The unique versatility over cryptomelane-based materials relies on the high porosity, acidity, hydrophobicity, electronic and ionic conductivities, and easy removal of lattice oxygen and recovery [15,23,24]. In addition, it has been well-reported that cryptomelane catalytic properties are improved by means of the introduction of different framework dopants, such as Cu [32–36], attributed to the weakening of the Mn–O bond in Mn–O–Cu bridges, resulting in the mobility and reactivity of the active oxygen species. [32,37–39].

Interestingly, another approach to improve catalytic performance is to disperse CuO particles on the external facets of cryptomelane structure via precursor copper salts deposition, seeking the formation of a binary catalytic system composed of CuO supported on cryptomelane (CuO/Cryptomelane) [40], in analogy to the outstanding well-reported CuO/CeO<sub>2</sub> catalysts, where special interfacial redox properties by means of synergistic effects result in an excellent performance [41,42].

Therefore, the goal of the current study presented herein along Chapter 5 deals with the critical investigation of CuO/Cryptomelane catalyst as an alternative to CuO/CeO<sub>2</sub> catalyst towards CO-PROX reaction. To this aim, cyclability and stability tests were conducted in order to study CuO/Cryptomelane performance and activity loss, besides the mechanism of deactivation and possible strategies to prevent such negative process to guarantee a feasible operation in CO-PROX reaction.

## **5.2 Experimental details**

### **5.2.1 Catalyst synthesis**

The synthesis of Cryptomelane catalyst was conducted following the well-reported reflux route [5], and the latter Cu loading (5% wt. Cu) by impregnation followed by calcination led to the preparation of CuO/Cryptomelane catalyst. Further details regarding procedures have been presented in [Section 2.1.1](#) from Chapter 2.

### **5.2.2 CO-PROX catalytic activity tests**

Cryptomelane and CuO/Cryptomelane catalysts were tested in CO-PROX catalytic tests according to the experimental settings and specific conditions as stated in [Section 2.2.3](#). Briefly, 100 ml/min of the CO-PROX gas mixture consisting in 2% CO, 2% O<sub>2</sub>, 30% H<sub>2</sub> in He balance ( $\lambda = 2$ ) was fed to the reactor with 150 mg of sample, and the experiment was conducted following heating rate of 2°C/min from 25 to 200°C. Consecutive catalytic cycles were performed in order to evaluate the stability of the catalysts, and after each catalytic cycle the catalysts were treated at 200°C or 400°C for 1 hour (heating rate 5°C/min) in 20 ml/min of 10% O<sub>2</sub>/He. Afterwards, the

reactor was cooled down to room temperature and a new catalytic cycle was conducted.

After four consecutive ramp CO-PROX experiments, a further isothermal CO-PROX experiment was also carried out using the same gas mixture (2 % CO, 2 % O<sub>2</sub>, 30 % H<sub>2</sub>, balance He). The temperatures were selected to obtain ca. 75 % CO conversion at the beginning of the isothermal experiments.

### 5.2.3 Catalysts characterization

Catalysts were characterized before and after the catalytic tests by means of X-ray photoelectron spectroscopy (XPS), Temperature programmed reduction with H<sub>2</sub> (H<sub>2</sub>-TPR), X-ray diffraction (XRD) and N<sub>2</sub> adsorption at -196°C, using DFT method for the determination of pore size distributions. All these techniques and procedures are explained in detail in Section 2.2.2 from Chapter 2.

## 5.3 Results and discussion

### 5.3.1 CO-PROX catalytic tests

Figure 5.1 shows results obtained with fresh catalysts in the CO-PROX reaction. Cryptomelane accelerates CO oxidation above 75°C and CuO loading lowers the onset temperature, CuO/Cryptomelane showing CO oxidation even at room temperature. This improvement of the cryptomelane performance upon CuO loading was already reported by Hernández et al.[26], and was attributed to a high lattice oxygen mobility due to the formation of Cu-O-Mn bridges.

**Figure 5.1.** CO conversion ( $X_{CO}$ ) in (solid symbols); and CO selectivity (Sel.) in (hollow symbols) obtained in CO-PROX experiments performed with fresh catalysts.

The CO conversion profile of CuO/Cryptomelane reached a maximum value near 100% at 130°C, and then decreased slowly with temperature. This drop of the CO conversion at high temperatures was already reported by other authors and was attributed to the competition between H<sub>2</sub> and CO oxidation and to the formation of hot spots (or higher local temperatures) as a consequence of the exothermic CO and H<sub>2</sub> oxidation reactions, which leads to the reversed WGS reaction and the subsequent CO formation [43,44].

Thus, the lower activation energy for CO oxidation when comparing to H<sub>2</sub> oxidation favours the preferential process only up to a critical temperature [42]. The selectivity profile of CuO/Cryptomelane reached a very high value (~96%) at relatively low temperature, and then decreased until an almost constant value of about 41%. It is important to highlight that a selectivity of 50% means that equal amounts of CO<sub>2</sub> (desired reaction) and H<sub>2</sub>O (side reaction) would be produced and that this is the maximum selectivity achievable at total O<sub>2</sub> consumption in the experimental conditions used (excess oxygen with  $\lambda=2$ ). Thus, even the relatively low selectivity remaining at high temperatures is high enough to obtain adequate fuel efficiency [44].

Once confirmed the excellent behaviour of the CuO/Cryptomelane catalyst, the stability was studied and four consecutive reaction cycles were performed with the CuO/Cryptomelane catalyst under the same experimental conditions used with the fresh catalyst (those indicated in the caption of Figure 5.1). For comparison, consecutive reaction cycles were also carried out with cryptomelane. As indicated in Section 5.2.2 from the present Chapter, after each reaction cycle the catalysts were reoxidized in 10% O<sub>2</sub>/He for 1 h. The reoxidation temperature was 200°C for cryptomelane while two temperatures were tested for CuO/Cryptomelane, 200 and 400°C.

The catalytic performance in four successive runs was studied for each reoxidation pre-treatment, and registered T<sub>50%</sub> temperatures, which is the temperature required to achieve 50% CO oxidation, are plotted in Figure 5.2.

**Figure 5.2.** Temperature for 50% CO conversion in consecutive CO-PROX reaction cycles.

Cryptomelane kept the same activity during the five consecutive reaction cycles, evidencing the high stability of this catalyst. On the contrary, CuO/Cryptomelane partially deactivated in consecutive cycles, and the temperature of the reoxidation step played an important role. Reoxidation of CuO/Cryptomelane at 400°C was more efficient than reoxidation at 200°C, and both temperatures allowed obtaining stable  $T_{50}$  values after the fourth CO-PROX reaction cycle. Despite the CuO/Cryptomelane deactivation in consecutive cycles, the stable  $T_{50}$  values obtained with the copper-containing catalyst in the fourth and fifth cycles were lower than those of cryptomelane, and the lowest values were obtained by reoxidation at 400°C.

These results in Figure 5.2 suggest that the decrease of the CO oxidation capacity of CuO/Cryptomelane, once used in the CO-PROX reaction, is related to changes in the copper species, since cryptomelane is stable. This hypothesis was also postulated by other authors [40,45] and will be discussed in more detail in the following sections.

### 5.3.2 Long-term catalytic tests

In order to evaluate the stability of the catalysts at constant temperature under CO-PROX reaction condition, long-term experiments were conducted after the fourth cycle. The temperatures of the isothermal experiments were selected to obtain ca. 75 % CO conversion.

The CO conversion, CO selectivity and temperature monitored during more than 10 hours are shown in Figure 5.3a for CuO/cryptomelane and in Figure 5.3b for cryptomelane, and both catalysts maintained quite stable behaviours. Only the CuO/Cryptomelane catalyst suffered a small drop of

CO conversion (~ 6 %) at the beginning of the experiment, which could be related to the presence of copper species because is not observed in copper-free cryptomelane.

**Figure 5.3.** Long-term CO-PROX experiments performed with **(a)** CuO/Cryptomelane and **(b)** Cryptomelane.

In conclusion, the ramp experiments showed that cryptomelane is stable while CuO/Cryptomelane partially deactivates in consecutive CO-PROX reaction cycles performed from room temperature up to 200°C. This deactivation was quite small in the long-term experiment performed at 145°C, indicating that transformations leading to partial deactivation occur above this temperature. The catalytic activity of CuO/Cryptomelane was partially restored reoxidizing the catalyst, and 400°C reoxidation was more effective than 200°C reoxidation.

### 5.3.3 XPS characterization

The ramp CO-PROX experiments suggested that changes in the copper species was the reason of the activity decay of the CuO/Cryptomelane catalyst in consecutive cycles, and XPS was used to analyze these changes during the experiments. Figure 5.4 shows the Cu2p region for fresh CuO/Cryptomelane and for this catalyst used in consecutive CO-PROX cycles with reoxidation treatments at 200°C or 400°C in between (XPS measurements were done after the fifth CO-PROX cycle). It is worth noting that the used catalyst was not reoxidized after the last CO-PROX cycle.

**Figure 5.4.** XPS spectra of CuO/Cryptomelane. **(a)** Cu2p region and **(b)** CuLMM Auger range.

The Cu 2p<sub>3/2</sub> photoemission of fresh catalyst showed a main contribution at 933.7 eV, typical of CuO [46], and the used catalyst additionally showed another contribution at 930.5-930.7 eV that must be assigned to copper species with different negative charge density. These low binding energy values have been reported for Cu-Mn mixed oxide with hopcalite structure (CuMn<sub>2</sub>O<sub>4</sub>) [47–49]. The main cations on hopcalite are Cu<sup>2+</sup> and Mn<sup>3+</sup>, but the presence of Cu<sup>+</sup> has been postulated due to the equilibrium  $\text{Cu}^{2+} + \text{Mn}^{3+} \leftrightarrow \text{Cu}^+ + \text{Mn}^{4+}$ . Evidences of the formation of hopcalite after the catalytic tests have been also obtained in the current study by XRD, as it will be discussed below.

These XPS results suggest that copper was fully oxidised as CuO on the fresh catalyst, which is not surprising because it was calcined for copper precursor decomposition, and part of this CuO was introduced into the hopcalite structure during the ramp CO-PROX experiments while part remained as CuO. The CuLMM Auger transition (Figure 4b) is quite similar in all spectra, being consistent with the presence of Cu(II). However, the relative contribution of the Cu<sup>2+</sup> satellite peak at 944 eV (Figure 5.4a) with regard to the Cu2p<sub>3/2</sub> peak at ~ 933.5 eV increases on the spectra obtained with the used catalyst reoxidized at 400°C with regard to that reoxidized at 200°C. This suggests higher population of Cu(II) cations upon 400°C reoxidation. Nevertheless, identification of the copper species by XPS is complex [50–53], and much more concluding evidences were obtained by H<sub>2</sub>-TPR, as discussed below.

The surface composition of the cryptomelane and CuO/Cryptomelane catalysts was also analyzed by XPS, and Table 5.1 compiles results of the K/Mn and Cu/Mn ratios obtained.

**Table 5.1.** Atomic surface composition of Cryptomelane and CuO/Cryptomelane determined by XPS.

Catalyst	K/Mn	Cu/Mn
<b>Cryptomelane fresh</b>	0.64	-
<b>Cryptomelane used</b> (Used in consecutive CO-PROX cycles with 200°C reoxidation in between)	0.52	-
<b>CuO/Cryptomelane fresh</b>	0.58	0.19
<b>CuO/Cryptomelane used</b> (without reoxidation)	0.59	0.23
<b>CuO/Cryptomelane</b> (Used in consecutive CO-PROX cycles with 200°C reoxidation in between)	0.65	0.12
<b>CuO/Cryptomelane</b> (Used in consecutive CO-PROX cycles with 400°C reoxidation in between)	0.83	0.06

The K/Mn ratio of cryptomelane slightly decreased after the CO-PROX ramp experiment, but this small surface modification does not affect the

catalytic performance. On the contrary, the K/Mn atomic ratio of CuO/Cryptomelane remained constant after the CO-PROX ramp experiment (without reoxidation) and increased during the consecutive CO-PROX experiments with reoxidation treatments in between, suggesting certain segregation of potassium to the surface. These results indicate that the segregation of K to the surface mainly occurs during the reoxidation treatments when copper is present. This segregation of K to the surface was similarly suggested by Veprek et al. [47] for commercial hopcalite tested as CO oxidation catalyst. Furthermore, Hu et al. [54] also described this phenomenon for silver-doped cryptomelane, and in our CuO/Cryptomelane catalyst occurred in a higher extent when the reoxidation between cycles was performed at 400°C than when was reoxidized at 200°C.

In addition, the Cu/Mn ratio decreased after the CO-PROX reactions performed with reoxidation treatments in between, and the minimum value was obtained for the catalyst reoxidized at 400°C between cycles. The reduction of this parameter can be an evidence of copper sintering.

These XPS results allowed concluding that the CuO/Cryptomelane catalyst suffered segregation of potassium to the surface and copper sintering, which could explain that the initial activity of the fresh catalyst was not fully recovered (see Figure 5.2) after the reoxidation treatments. More information about these transformations was obtained by complementary characterization techniques that are discussed in the coming sections.

#### **5.3.4 H<sub>2</sub>-TPR characterization**

Since the redox processes occurring on CuO/Cryptomelane seem to be behind the partial deactivation of this catalyst in consecutive CO-PROX ramp experiments, H<sub>2</sub>-TPR characterization was carried out to get further insight into such processes. Figure 5.5 compiles the H<sub>2</sub> reduction profiles obtained with the cryptomelane and CuO/Cryptomelane catalysts tested as prepared (fresh) and after CO-PROX experiments (after the fifth CO-PROX cycle).

The H<sub>2</sub>-TPR profiles obtained with fresh and used cryptomelane are equal (top profiles in Figure 5.5), with a single peak with maxima at 400°C and a low-temperature shoulder evidencing that several events were taking place. This is consistent with the high stability of this material in consecutive ramp CO-PROX experiments (Figure 5.2). Note that the onset H<sub>2</sub> reduction temperature in H<sub>2</sub>-TPR experiments (~ 270°C) was well above the maximum temperature achieved in the ramp CO-PROX experiments (200°C).

The consumption of H<sub>2</sub> by cryptomelane in H<sub>2</sub>-TPR experiments is attributed to the reduction of manganese cations, initially present mainly in +4 and +3 oxidation states, giving MnO as the final product of the reduction processes [55]. It is known that the reduction progresses throughout the following sequence:  $\text{MnO}_2 \rightarrow \text{Mn}_2\text{O}_3 \rightarrow \text{Mn}_3\text{O}_4 \rightarrow \text{MnO}$ , though it is not easy

to discern each step due to the experimental conditions and to the local environment of the reducible species [9,26,56]. Hence, cryptomelane has a complex reduction profile with several chemical transformations appearing under the same peak [32,33,57,58]. Typically, the H<sub>2</sub> reduction profiles of cryptomelane described in bibliography, which are similar to those on Figure 5.5, consist of a shoulder at about 340°C, assigned to the reduction of surface cations, followed by a main peak attributed to bulk transformations of MnO<sub>2</sub>/Mn<sub>2</sub>O<sub>3</sub> to Mn<sub>3</sub>O<sub>4</sub>, and Mn<sub>3</sub>O<sub>4</sub> to MnO, which overlap in the H<sub>2</sub>-TPR profile.

**Figure 5.5.** H<sub>2</sub> reduction profiles obtained with Cryptomelane and CuO/Cryptomelane catalysts tested as prepared (fresh) and after CO-PROX experiments (after the fifth CO-PROX cycle). In some cases, the used CuO/Cryptomelane catalyst was reoxidized in situ (in the H<sub>2</sub>-TPR device) at 200 or 400°C (at the same temperature used in each case in consecutive CO-PROX cycles for reoxidation between cycles).

The H<sub>2</sub> reduction profile of fresh CuO/Cryptomelane (bottom curve on Figure 5.5) had some differences with regard to that of bare cryptomelane (top curve on Figure 5.5). A H<sub>2</sub> consumption peak was observed at 200°C associated to the reduction of disperse CuO particles. It must be taken into account that bulk CuO is reduced above 350°C [46], and the shift to lower

temperature in CuO/Cryptomelane must be attributed to the effect of the cryptomelane support [59,60]. In addition, the reduction of cryptomelane also took place at lower temperature in CuO/Cryptomelane (maximum at 380°C) than in bare cryptomelane (400°C). It has been reported that the addition of copper leads to the creation of  $\text{Cu}^{2+}\text{-O-Mn}^{\gamma+}$  entities that promote the oxygen lability with partial delocalization of the Mn – O bond, improving manganese reducibility [9,26,32,33,40]. Such lability is related to a high structural and superficial oxygen mobility, and this is positive for oxidation reactions occurring throughout a Mars-van Krevelen (MVK) mechanism, which is usually accepted for these kind of catalysts [30,40,61]. In the reaction studied in this article, it is expected that CO was oxidised by catalyst oxygen forming oxygen vacancies that were filled up by gas phase molecular oxygen afterwards [62].

Moreover it has been reported that metallic Cu has a catalytic effect on the dissociation of the  $\text{H}_2$  molecule, and enhances the reduction of interfacial manganese cations by hydrogen *spillover* [32,60,63]. This effect is strongly dependent on the CuO dispersion [64,65]. The catalytic effect of metallic copper would explain the shift of the main manganese reduction peak from 400 to 380°C.

The  $\text{H}_2$  reduction profile of fresh CuO/Cryptomelane changed after the ramp CO-PROX reaction (see reduction profile of used CuO/Cryptomelane in Figure 5). The peak at 200°C associated to the reduction of highly dispersed CuO species disappeared, indicating that CuO was reduced under the reaction conditions of the CO-PROX ramp experiments. Instead, two little reduction events were identified at 240 and 280°C, probably due to the reduction of CuO aggregates with two different sizes [40] that remained oxidised after the CO-PROX experiments. Additionally, the main band at 380-400°C attributed to manganese cations reduction was also different for fresh and used CuO/Cryptomelane. The low-temperature shoulder observed in the fresh catalyst became a well-defined peak in the used catalyst. This could indicate that oxygen species were accumulated on the catalyst surface during the CO-PROX reaction, which would be reduced in the  $\text{H}_2$ -TPR experiments, and the desorption of carbonate/bicarbonate species accumulated on the catalyst as CO oxidation intermediates cannot be ruled out.

The reoxidation of the used CuO/Cryptomelane catalyst at 200°C had a little effect on the  $\text{H}_2$  reduction profile. The low temperature CuO reduction peak remained missing, evidencing that this temperature was not high enough to reoxidize copper. The main difference in the  $\text{H}_2$  reduction profiles of the used CuO/Cryptomelane catalyst before and after reoxidation at 200°C was the decrease of the peak at 340°C, which would indicate that this reoxidation treatment removed surface species accumulated during the CO-PROX reaction.

Nevertheless, used CuO/Cryptomelane reoxidation at 400°C leads to the oxidation of reduced copper, and a H<sub>2</sub> reduction peak appeared at 240°C. This temperature was higher than that on the fresh catalyst (200°C), and the worse reducibility of CuO after reduction and reoxidation would explain the partial decrease of the CO oxidation capacity in consecutive CO-PROX cycles (see Figure 5.2). This delay of the CuO reduction peak after reoxidation at 400°C could be due to the worse CuO-cryptomelane interaction [48,66,67] and would be consistent with the evidences of copper sintering provided by XPS (see Table 5.1).

### 5.3.5 Characterization by XRD and N<sub>2</sub> adsorption-desorption

The structural transformations of the catalysts during the ramp CO-PROX experiments were studied, and Figure 5.6 shows the X-Ray powder diffraction (XRD) patterns of fresh and used cryptomelane and CuO/Cryptomelane. All diffractograms showed the main reflexions of the Cryptomelane structure, while evidences of the CuO peaks were not observed in the diffractograms of CuO/Cryptomelane. This indicated that CuO aggregates must consist of small crystallites [68].

**Figure 5.6.** X-Ray powder diffraction patterns for fresh and spent Cryptomelane-based catalysts. Caption: (\*) Cryptomelane (JCPDS card no. 29-1020); (Δ) CuMn<sub>2</sub>O<sub>4</sub>, (JCPDS card no. 45-0505); (■) Mn<sub>3</sub>O<sub>4</sub>, Hausmannite (JCPDS card no. 24-0734); (□) CuO (JCPDS card no. 80-1268).

The cryptomelane catalyst showed the same diffractogram before and after the ramp CO-PROX experiments, which was in good agreement with the high stability of this material under reaction conditions (see Figure 5.2).

On the contrary, an additional peak appeared on the diffractogram of CuO/Cryptomelane after the CO-PROX experiments that could be attributed to hausmannite ( $\text{Mn}_3\text{O}_4$ ) and/or to hopcalite ( $\text{CuMn}_2\text{O}_4$ ). Cryptomelane, hausmannite and hopcalite are based on tetragonal structures, and seldom transitions can take place as a consequence of partial reduction of manganese cations and/or due to the sintering of copper particles to form copper-manganese mixed oxide aggregates. These transformations are in agreement with the surface restructuring observed by XPS (Table 5.1) and with the delay of the copper species reduction peak in  $\text{H}_2$ -TPR experiments to higher temperatures (Figure 5.5), and also explain why the CO oxidation capacity of CuO/Cryptomelane was not fully recovered after reoxidation at  $400^\circ\text{C}$  (Figure 5.2).

Finally, selected samples were characterized by  $\text{N}_2$  adsorption-desorption at  $-196^\circ\text{C}$ . Figure 5.7 includes the  $\text{N}_2$  adsorption-desorption isotherms for fresh Cryptomelane, fresh CuO/Cryptomelane and CuO/Cryptomelane used in 5 consecutive CO-PROX cycles with  $400^\circ\text{C}$  reoxidation in between. The obtained specific surface areas and pore volumes are compiled in Table 5.2.

**Figure 5.7.**  $\text{N}_2$  adsorption-desorption isotherms ( $-196^\circ\text{C}$ ) characterization for fresh Cryptomelane, fresh CuO/Cryptomelane and used CuO/Cryptomelane in 5 consecutive CO-PROX cycles with  $400^\circ\text{C}$  reoxidation in between.

**Table 5.2.** Catalyst characterization by gas adsorption–desorption

Catalyst	S <sub>BET</sub> (m <sup>2</sup> /g)	V <sub>DR</sub> (N <sub>2</sub> ) (cm <sup>3</sup> /g)	V <sub>DR</sub> (CO <sub>2</sub> ) (cm <sup>3</sup> /g)
<b>Cryptomelane fresh</b>	73	0.03	0.02
<b>CuO/Cryptomelane fresh</b>	59	0.02	0.01
<b>CuO/Cryptomelane</b> (Used in consecutive CO-PROX cycles with 400°C reoxidation in between)	55	0.02	-

Cryptomelane showed a type IV N<sub>2</sub> adsorption isotherm, with a hysteresis loop in the high relative pressure range, which according to the IUPAC classification is typical of mesoporous materials. Cryptomelane-based materials show a type H3 hysteresis, as it does not exhibit any limiting adsorption at high P/P<sub>0</sub>, and this is typical of non-rigid aggregates of plate-like particles giving rise to slit-shaped pores [69].

The N<sub>2</sub> adsorption-desorption isotherms of fresh and used CuO/Cryptomelane were qualitatively similar to that of cryptomelane, but with a slightly lower adsorption at low relative partial pressures. This decrease must be attributed to the partial porosity blocking by CuO. The surface area values are also consistent with the decrease produced upon CuO loading, being 73 m<sup>2</sup>/g for Cryptomelane and 59 m<sup>2</sup>/g for CuO/Cryptomelane, and these values are in agreement with those reported by other authors [21,30,40,70]. Further changes in the porosity of the CuO/Cryptomelane catalyst during the ramp CO-PROX reactions were negligible, indicating that the restructuring detected by XPS and XRD does not affect the porosity.

## 5.4 Conclusions

In conclusion, the study of Cryptomelane and CuO/Cryptomelane catalysts in the CO-PROX reaction, paying special attention to deactivation and regeneration, has shown that:

(1) Cryptomelane was stable during CO-PROX reactions in ramp experiments until 200°C and in a long-term isothermal experiment (10 h). Changes neither in the H<sub>2</sub> reducibility and porosity nor in the crystalline phases detected by XRD were observed.

(2) CuO/Cryptomelane partially deactivated in consecutive CO-PROX reaction cycles performed until 200°C, and the catalytic activity was partially restored reoxidising the catalyst at 200°C or 400°C, the latter temperature being more effective.

(3) In spite of the CuO/Cryptomelane partial deactivation, the catalytic CO-PROX activity of this catalyst was higher to that of Cryptomelane once a stable behaviour was achieved.

(4) The partial deactivation of CuO/Cryptomelane was related to the segregation of crystalline phases (hausmannite ( $\text{Mn}_3\text{O}_4$ ) and/or to hopcalite ( $\text{CuMn}_2\text{O}_4$ )), with segregation of potassium to the surface and decrease of the copper cations reducibility. The potential contribution to deactivation of changes in the porous texture of the CuO/Cryptomelane catalyst has been ruled out.

As these results bring promising opportunities for CuO/Cryptomelane catalyst when the appropriate reoxidation treatment is conducted. The following Chapter focuses on the study of CuO/Cryptomelane catalyst in real CO-PROX operation conditions, including  $\text{H}_2\text{O}$  and  $\text{CO}_2$  in the reaction mixture together with CO and  $\text{H}_2$ .

## CHAPTER 6

# Effect of CO<sub>2</sub> and H<sub>2</sub>O in the catalytic performance of CuO/Cryptomelane for the preferential oxidation of CO

The catalytic activity of CuO/Cryptomelane in CO-PROX reaction has been studied in the absence and presence of H<sub>2</sub>O and CO<sub>2</sub>, paying special attention to the catalyst stability and to changes on its physical-chemical properties. For fresh CuO/cryptomelane catalyst, the presence of CO<sub>2</sub> and/or H<sub>2</sub>O in the CO-PROX feed partially inhibits CO oxidation due to chemisorption of H<sub>2</sub>O and CO<sub>2</sub> on the catalyst. H<sub>2</sub>O chemisorption on CuO/Cryptomelane is stronger than CO<sub>2</sub> chemisorption, and simultaneous CO<sub>2</sub> and H<sub>2</sub>O adsorption has a synergistic effect that enhances co-adsorption and significantly hinders CO oxidation. On the contrary, the presence of CO<sub>2</sub> + H<sub>2</sub>O in the CO-PROX reaction mixture has a positive effect in the CuO/Cryptomelane stability upon several consecutive reaction cycles in the 25-200°C range. XRD showed that chemisorbed CO<sub>2</sub> + H<sub>2</sub>O species partially prevent the catalyst deactivation due to cryptomelane reduction to hausmannite (Mn<sub>3</sub>O<sub>4</sub>) under the strongly reductive environment of the CO-PROX reaction, and H<sub>2</sub>-TPR and Raman spectroscopy characterization support that the cryptomelane structure is less damaged under CO-PROX conditions in the presence of CO<sub>2</sub> and H<sub>2</sub>O than in the absence of these species. Therefore, interestingly under CO<sub>2</sub> + H<sub>2</sub>O environment (realistic CO-PROX conditions) CuO/Cryptomelane catalyst performs an improved catalytic activity once stable behavior is reached.

## 6.1 Introduction

In the previous Chapter, a CuO/Cryptomelane catalyst was tested in CO-PROX reaction with a CO + H<sub>2</sub> + O<sub>2</sub> gas mixture, and an exceptional performance was found [1]. However, its catalytic activity lowered in successive cycles of reaction, despite regeneration steps were conducted between cycles. Such deactivation was associated to partial collapse of cryptomelane structure produced by potassium segregation and copper sintering under CO-PROX reaction conditions. Despite this loss of activity, the remaining activity of CuO/Cryptomelane catalyst showed a good potential for CO-PROX oxidation under the reaction conditions of that study.

The effect of CO<sub>2</sub> and H<sub>2</sub>O in the CO-PROX reaction feed in the activity, selectivity and stability of CuO/Cryptomelane was not evaluated in our previous study [1], and it is known the detrimental effect of these inhibitors in many CO-PROX catalysts, such as CuO/Ceria [2]. The study from Hernández et al. [3] was pioneer in undergoing CO-PROX real conditions using Cryptomelane. These authors evaluated the activity of Cu-modified cryptomelane for CO-PROX reaction with the addition of CO<sub>2</sub>, H<sub>2</sub>O and CO<sub>2</sub> + H<sub>2</sub>O in the reaction mixture, concluding that CO<sub>2</sub> partially inhibits the activity while H<sub>2</sub>O inhibits or enhances the activity depending on the reaction temperature. The inhibiting effect of CO<sub>2</sub> and H<sub>2</sub>O was attributed to the blockage of CO chemisorption sites while the positive effect of H<sub>2</sub>O above a critical temperature was explained appealing to the thermodynamics of parallel reactions that could take place in presence of water, such as the Reverse Water Gas Shift reaction [4], and to the formation of labile intermediates of fast desorption by means of the surface hydroxyl groups. As far as we know, the stability of CuO/Cryptomelane catalysts under CO-PROX reaction conditions including CO<sub>2</sub> and H<sub>2</sub>O in the reaction mixture has not been studied so far, and this is a critical issue for the potential application of this promising catalysts in real devices. Therefore, the goal of this study is to analyse the stability of CuO/Cryptomelane catalyst under realistic CO-PROX conditions including CO<sub>2</sub>, H<sub>2</sub>O and CO<sub>2</sub> + H<sub>2</sub>O in the gas mixture, not only paying attention to the effect of these species on the chemical processes occurring under reaction conditions but also to changes on the physical-chemical properties of the catalyst in consecutive reaction tests.

## 6.2 Experimental details

The synthesis of CuO/Cryptomelane catalyst (5% wt. Cu) was conducted following the well-reported reflux route [5] according to the previously procedure detailed in [Section 2.1.1](#) from Chapter 2.

. The prepared CuO/Cryptomelane was tested in CO-PROX catalytic tests according to the experimental settings and specific conditions as stated in [Section 2.2.3](#). Briefly, 100 ml/min of the CO-PROX gas mixture consisting

in 2% CO, 2% O<sub>2</sub>, 30% H<sub>2</sub> in He balance ( $\lambda = 2$ ) was fed to the reactor with 150 mg of sample, and the experiment was conducted following heating rate of 2°C/min from 25 to 200°C. The effect of inhibitors was studied, too, performing different catalytic cycles in the set of conditions: CO+H<sub>2</sub>+O<sub>2</sub>; CO+H<sub>2</sub>+O<sub>2</sub>+CO<sub>2</sub>; CO+H<sub>2</sub>+O<sub>2</sub>+H<sub>2</sub>O; and CO+H<sub>2</sub>+O<sub>2</sub>+CO<sub>2</sub>+H<sub>2</sub>O, conducted by means of the introduction, either separated or together, of 9% CO<sub>2</sub> and 5% H<sub>2</sub>O in the reactant gas mixture feeding.

The chemical adsorption of CO<sub>2</sub> and H<sub>2</sub>O on CuO/Cryptomelane catalysts was studied by means of temperature programmed desorption (TPD), performing saturation steps over pre-treated sample in 100 ml/min of 10% CO<sub>2</sub>/Ar (for CO<sub>2</sub>-TPD), 5% H<sub>2</sub>O/Ar (for H<sub>2</sub>O-TPD) or 10% CO<sub>2</sub> + 5%H<sub>2</sub>O/Ar (for CO<sub>2</sub>+H<sub>2</sub>O-TPD). Fresh and spent catalyst samples were analyzed by means of temperature programmed reduction with H<sub>2</sub> (H<sub>2</sub>-TPR), X-ray diffraction (XRD), and Raman spectroscopy. Further details regarding the experimental settings can be found in [Section 2.2.2](#) from Chapter 2.

## **6.3 Results and discussion**

### **6.3.1 CO-PROX reaction catalytic tests**

Figure 6.1 shows the CO conversion (Figure 6.1a) and CO selectivity (Figure 6.1b) profiles in the ramp experiments conducted in CO-PROX conditions for the fresh CuO/Cryptomelane catalyst (first run) under the different atmospheres tested.

According to Figure 6.1, the gas mixture composition strongly affects the catalytic activity. The catalyst showed the best performance when tested under CO + H<sub>2</sub> + O<sub>2</sub> mixture, reaching its maximum CO conversion of 95% at 125°C and keeping after that temperature a stable conversion of 88%. Such CO conversion decay coincides with a loss of CO oxidation selectivity towards the competitive reaction of H<sub>2</sub> oxidation, which reaches an acceptable constant value of 44% (being 50% the maximum selectivity that can be achieved given the O<sub>2</sub> stoichiometric excess,  $\lambda=2$ ). This was the expected behaviour of this catalyst for these experimental conditions, as discussed in the previous chapter, and is in good agreement with the behaviour previously reported on literature [3,6]

**Figure 6.1.** CO-PROX experiments performed with fresh catalyst (first run for each gas mixture) under gas mixtures of different composition. **(a)** CO conversion ( $X_{CO}$ ) and **(b)** CO selectivity (Sel.).

The addition of  $CO_2$  to the reactant mixture slightly decreases the catalytic activity, shifting the CO conversion and CO selectivity profiles towards higher temperatures. The inhibitor effect of  $CO_2$  in many CO-PROX catalysts is well-known [3,7], but in this case, our CuO/Cryptomelane catalyst is only minimally affected. On the contrary, results on Figure 1 evidence that  $H_2O$  strongly affects CO oxidation, delaying the CO oxidation curve about 25 $^{\circ}C$ , and the experiment performed with  $CO + H_2 + O_2 + CO_2 + H_2O$  reveals a synergy between the  $CO_2$  and  $H_2O$  inhibiting effects.

Some authors suggested that the presence of  $H_2O$  and/or  $CO_2$  in the CO-PROX reaction mixture does not affect the mechanism of reaction for transition metal (Co, Cr, Cu, Ni, Zn) catalysts supported on oxides with very different nature ( $MgO$ ,  $La_2O_3$ ,  $SiO_2-Al_2O_3$ ,  $CeO_2$ ,  $Ce_{0.63}Zr_{0.37}O_2$ ), as CO selectivity profile is not modified in any case, just shifting in temperature in the same way than CO conversion [8]. These conclusions are also in agreement with those of Hernández et al. [16] for Cu-modified Cryptomelane

CO-PROX catalysts, but these authors additionally reported the contribution of parallel reactions involving H<sub>2</sub>O above a certain temperature.

Assuming that the inhibition processes can be associated to chemisorption of H<sub>2</sub>O and CO<sub>2</sub> on the CuO/Cryptomelane catalyst, our results indicate that H<sub>2</sub>O chemisorption on CuO/Cryptomelane is stronger than CO<sub>2</sub> chemisorption. H<sub>2</sub>O chemisorption could take place both in the external surface of cryptomelane and/or into the channels. External chemisorption of H<sub>2</sub>O (and CO<sub>2</sub>) is expected to compete with CO chemisorption, while H<sub>2</sub>O chemisorption into the channels will increase the amount of structural water decreasing the population of oxygen vacancies and oxygen mobility.

According to literature results obtained for other CO-PROX catalysts [29], surface CO<sub>2</sub> chemisorption probably leads to the formation of mono- and/or bidentate carbonates on the catalyst surface, H<sub>2</sub>O is expected to lead to the formation of hydroxyl groups, and simultaneous CO<sub>2</sub> and H<sub>2</sub>O chemisorption will probably form a mixture of carbonate and bicarbonate species [9]. Unfortunately, all our attempts to identify such chemisorbed species by *in situ* DRIFTS experiments failed due to the high adsorption of IR radiation by the CuO/Cryptomelane catalyst because of its dark black colour.

In order to check the stability of the CuO/Cryptomelane catalyst under the catalytic conditions tested, four consecutive cycles of reaction were carried out (without any regeneration treatment between cycles). The CO conversion and selectivity profiles obtained were qualitatively similar to those compiled in Figure 6.1, and only changed the temperatures depending on the gas mixture and run number. Figure 6.2 compiles the temperatures for 50% CO conversion in these experiments.

**Figure 6.2.** Temperature for 50% of CO conversion in consecutive reaction cycles under gas mixtures of different composition.

In accordance to our previous conclusions [24], the catalytic activity in  $\text{CO} + \text{H}_2 + \text{O}_2$  decreases after the first run, and this was attributed to the segregation of crystalline phases (hausmannite ( $\text{Mn}_3\text{O}_4$ ) and/or hopcalite ( $\text{CuMn}_2\text{O}_4$ )), with the segregation of potassium to the surface and decrease in the copper cations' reducibility. Figure 6.2 shows that the effect of adding  $\text{CO}_2$  to the reaction atmosphere in CO oxidation in consecutive cycles is negligible.

On the contrary, deactivation in consecutive cycles occurs more gradually in the presence of  $\text{H}_2\text{O}$ , leading to a steady state in the fourth cycle similar to that achieved with  $\text{CO} + \text{H}_2 + \text{O}_2$  (with and without  $\text{CO}_2$ ). Therefore, the presence of  $\text{H}_2\text{O}$  seems to affect the kinetics of changes occurring on the catalyst leading to partial deactivation. Such positive impact is even more evident when  $\text{CO}_2$  and  $\text{H}_2\text{O}$  are added simultaneously, since the catalyst reaches a stable behaviour after the third cycle with a  $T_{50}$  temperature lower to that achieved under all other gas mixtures tested. In the presence of  $\text{CO}_2 + \text{H}_2\text{O}$ , the catalytic activity is clearly inhibited on the first run, but the moderate deactivation occurring along further cycles leads to the best performance after four cycles of reaction. Hence, in these conditions,  $\text{CO}_2$  is facilitating  $\text{H}_2\text{O}$ -cryptomelane interaction, which is being positive for the maintenance of the catalyst integrity. Thus, despite the negative blocking of the catalyst surface by  $\text{CO}_2$  and  $\text{H}_2\text{O}$  and the consequent initial inhibition of the catalytic activity, the incorporation of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  is, in the end, positive to perform CO-PROX in CuO/Cryptomelane in further reaction cycles.

### 6.3.2 Temperature Programmed Desorption (TPD) experiments

In order to study the  $\text{CO}_2$  and  $\text{H}_2\text{O}$  chemisorption on CuO/Cryptomelane, TPD experiments were conducted after saturation of the catalyst with  $\text{CO}_2$  ( $\text{CO}_2$ -TPD),  $\text{H}_2\text{O}$  ( $\text{H}_2\text{O}$ -TPD), and  $\text{CO}_2 + \text{H}_2\text{O}$  ( $\text{CO}_2+\text{H}_2\text{O}$ -TPD). Additionally, a control experiment was carried out omitting the saturation step previous to TPD. The control experiment allows discerning the effect of the saturation steps from the inherent decomposition of the fresh material. Figure 6.3 shows the results obtained in all TPD experiments conducted, following by mass spectrometry the  $m/z$  signals 44, 18 and 32, corresponding to  $\text{CO}_2$ ,  $\text{H}_2\text{O}$  and  $\text{O}_2$ , respectively.

Two regions must be distinguished on Figure 6.3, below and above  $450^\circ\text{C}$  approximately. Cryptomelane structure starts decomposing to  $\text{Mn}_2\text{O}_3$  at temperatures around  $500^\circ\text{C}$ , the actual temperature depending on the atmosphere and particle size [10]. This is consistent with the release of  $\text{O}_2$  observed in Figure 3c, and previous saturation of the catalysts with  $\text{CO}_2$  and/or  $\text{H}_2\text{O}$  has a minor effect on the release of  $\text{O}_2$  in the experimental conditions of these experiments. Below  $500^\circ\text{C}$ , the cryptomelane structure is maintained but a loss of the water bounded to the cryptomelane nanofibers takes place together with desorption of the chemisorbed species.

**Figure 6.3.** TPD experiments performed in Ar after saturation of the  $\text{CuO}/\text{Cryptomelane}$  catalyst with  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ , or  $\text{CO}_2 + \text{H}_2\text{O}$  (control = no previous saturation). **(a)**  $\text{CO}_2$  release, **(b)**  $\text{H}_2\text{O}$  release and **(c)**  $\text{O}_2$  release.

After saturation with  $\text{CO}_2$ , a  $\text{CO}_2$  evolution peak centred at  $215^{\circ}\text{C}$  is observed on the TPD profile (Figure 6.3a), which is associated to the decomposition of carbonates formed during the saturation step. The intensity of this peak increases drastically upon saturation with a mixture of  $\text{CO}_2 +$

H<sub>2</sub>O, indicating that the presence of H<sub>2</sub>O significantly enhances CO<sub>2</sub> chemisorption.

Besides, it can be discerned in Figure 6.3b two types of chemisorbed H<sub>2</sub>O species that are desorbed in the ranges 150-300°C and 300-375°C, corresponding to the evolution of surface-related water and water bounded inside the 2x2 tunnels, respectively. On the other hand, CO<sub>2</sub>-TPD and H<sub>2</sub>O-TPD experiments show that cryptomelane has a clear preference towards water interaction and is capable to chemisorb water in the narrow tunnel with strong adsorption potential due to the micropore filling, which is in agreement with the study of Kijima et al. [11].

When CO<sub>2</sub> and H<sub>2</sub>O are added simultaneously in the saturation step, the emission profiles for the signals 44 and 18 change in a great measure, displaying a coupled CO<sub>2</sub> and H<sub>2</sub>O evolution and evidencing the magnification of the chemisorption capacity of cryptomelane towards these species when added together rather than in separate environments. Below 450°C, the sharp CO<sub>2</sub> peak can be matched to the H<sub>2</sub>O evolution in the same temperature window, which is associated to the desorption of bicarbonate species that are thermodynamically less stable and more labile than carbonates [9]. The preferential formation of bicarbonates rather than carbonates in the presence of H<sub>2</sub>O upon CO<sub>2</sub> chemisorption gives rise to a different interaction with the catalyst, which improves its chemisorption capacity towards carbon-based species. Thus, the m/z 18 peak in the 300-375°C range observed in the experiment with H<sub>2</sub>O saturation, which is assigned to H<sub>2</sub>O occluded inside the tunnels, is not visible upon CO<sub>2</sub> + H<sub>2</sub>O co-chemisorption, suggesting that H<sub>2</sub>O is instead forming bicarbonate intermediates that cannot enter the narrow pores of the structure.

As a conclusion, TPD experiments have shown the synergistic effect between CO<sub>2</sub> and H<sub>2</sub>O towards the formation of chemisorbed species, which can be critical in the catalytic process. These TPD results (Figure 6.3) are in agreement with the observed catalytic activities during the first cycle of CO-PROX experiments performed under different gas mixtures (Figure 6.1), where CO<sub>2</sub> has almost no influence, H<sub>2</sub>O inhibits the activity by blocking active sites and/or decreasing oxygen vacancies and CO<sub>2</sub>+H<sub>2</sub>O inhibit in higher extent by means of forming a larger amount of chemisorbed species with stronger interaction with cryptomelane. However, this negative effect of CO<sub>2</sub> and H<sub>2</sub>O co-chemisorption during the first cycle of catalytic tests (see Figure 2) becomes positive effect in further cycles, and the reasons are discussed in the coming section.

### 6.3.3 Characterization of fresh and used catalysts

Figure 6.4 shows X-Ray diffraction patterns for the fresh CuO/Cryptomelane catalyst and once used in four consecutive reactions with CO + H<sub>2</sub> + O<sub>2</sub> + CO<sub>2</sub> + H<sub>2</sub>O and with CO + H<sub>2</sub> + O<sub>2</sub>. In all cases, the CuO

tenorite diffraction peaks are not distinguished, but important changes in the diffraction pattern of the cryptomelane support are observed in the fresh and used samples.

**Figure 6.4.** XRD diffraction patterns for the CuO/Cryptomelane catalysts. Caption: (□) Cryptomelane: JCPDS card no. 29-1020; (▲) Hausmannite: JCPDS card no. 24-0734.

The X-Ray diffraction patterns shown in Figure 6.4 prove that the deactivation of the CuO/Cryptomelane catalyst depends on the reaction gas mixture composition. Once the catalyst was used in CO-PROX cycles in absence of CO<sub>2</sub> and H<sub>2</sub>O, the main crystallite phase is not cryptomelane, but hausmannite (Mn<sub>3</sub>O<sub>4</sub>). This indicates that the strongly reductive environment of the CO-PROX reaction at the maximum temperature is able to reduce the manganese in the cryptomelane (K<sub>x</sub>Mn<sub>8</sub>O<sub>16-x</sub>) structure up to some extent.

Previously, in Chapter 5 [1], it has been discussed the deactivation process and the possible strategies of regeneration of the CuO/Cryptomelane catalyst in CO-PROX reaction, concluding that partial recovery is achieved by reoxidation pre-treatments at 400°C in between. In addition, the presence of CuO nanoparticles on the surface was critical for the catalyst performance, which improved its catalytic activity when comparing to raw cryptomelane, but the stability was dramatically affected during the reactions. Accordingly, the reducibility of CuO/Cryptomelane was largely increased with regards to bare Cryptomelane, so its catalytic activity, but also the susceptibility to deactivation by reduction under CO-PROX conditions. Thus, even undertaking the reoxidation treatments between cycles, it was not possible to restore completely the original catalytic activity, as a consequence of the partial collapse of cryptomelane structure by means of K segregation and the collateral sintering of CuO nanoparticles, occurring at the high temperature of such regeneration procedures.

In this particular study, however, the regeneration issues are not taken into account, and the catalyst was tested during four reaction cycles without any pre-treatment between them in all the series conducted. According to Figure 6.3, CuO/Cryptomelane catalyst is less damaged after used in reaction when CO<sub>2</sub> and H<sub>2</sub>O are present in the gas mixture, as cryptomelane peaks are still observed in the diffractogram. Then, the better performance after several uses in these conditions is necessarily associated to the catalyst stability and, consequently, reutilisation, aspects that have been studied for the first time in Cryptomelane-based catalysts under real CO-PROX reaction.

The H<sub>2</sub>-TPR characterization of the CuO/Cryptomelane catalyst, both fresh and used, evidence as well a higher stability during CO-PROX experiments performed with CO<sub>2</sub> + H<sub>2</sub>O in the feed (results shown in Figure 6.4j5), which is in agreement with the XRD characterization.

**Figure 6.5.** H<sub>2</sub>-TPR results for the CuO/Cryptomelane samples. 40 mg of catalyst, 40 ml/min 5% H<sub>2</sub>/Ar, 10°C/min.

It is well known that cryptomelane presents a H<sub>2</sub> reduction profile which is based on multiple reduction steps until the final state of 2+ for manganese [12]. The presence of copper oxide modifies the reduction profile observable

by the shift towards lower temperatures, produced by means of a synergistic effect between Cu and Mn. As well, CuO is also more easily reduced when it is finely dispersed onto cryptomelane support, when comparing to bulk CuO [1]. Hence, in fresh CuO/Cryptomelane can be distinguished a reduction peak with maxima at 192°C, which corresponds to the anticipated reduction of the CuO dispersed phase. This reduction peak is characteristic from the initial dispersion of CuO present in the catalyst at the beginning of the reaction. This CuO reduction peak is not discernible in the profiles for the used samples, which is shifted towards higher temperatures and overlapped under the reduction of bulk manganese, giving rise to the mixed reduction peaks centred between 265°C and 320°C in the used samples. This suggests that, under CO-PROX reaction conditions, the CuO phase is partially sintered, lowering the Cu-Mn interaction [13], or reduced to a degree.

Nevertheless, the most explicit differences between the reduction profiles are relative to the reduction process for manganese in cryptomelane. The H<sub>2</sub> reduction profile of the catalysts used in CO-PROX experiments performed with CO<sub>2</sub> and H<sub>2</sub>O in the feed is qualitatively similar to the one for the fresh sample, but with lower area. The two main peaks observed in these profiles are assigned to the reduction of cryptomelane in two steps: (i) to Mn<sub>2</sub>O<sub>3</sub>/Mn<sub>3</sub>O<sub>4</sub>; (ii) to MnO. On the contrary, the H<sub>2</sub> reduction profile of the sample tested in CO-PROX experiments in absence of CO<sub>2</sub> and H<sub>2</sub>O presents totally different shape. The sharp peak centred at 408°C is an evidence of the loss of Cu-Mn interaction and of the formation of Mn<sub>3</sub>O<sub>4</sub>, which is reduced in one step to MnO.

As a conclusion, H<sub>2</sub>-TPR characterization confirms the greater stability of CuO/Cryptomelane during CO-PROX reactions performed with CO<sub>2</sub> + H<sub>2</sub>O in the feed, which presents partial degradation but keeps cryptomelane integrity up to an extent, which is not shown by the sample tested in CO-PROX experiments under the CO<sub>2</sub>- and H<sub>2</sub>O-free stream.

Raman spectra compiled on Figure 6.6 are consistent with these conclusions, and also support the higher stability of the CuO/Cryptomelane catalyst during the CO-PROX experiments performed with CO<sub>2</sub> and H<sub>2</sub>O in the feed. The interpretation of the entire Raman spectra for cryptomelane-based crystalline structure is not trivial, as well as for the wide range of existing manganese oxides [14,15].

**Figure 6.6.** Raman spectra of the fresh and used samples for CuO/Cryptomelane catalyst.

Cryptomelane is based on a body-centered tetragonal structure with space group  $I4/m$  [16] and its Raman spectrum features four main contributions at 183, 386, 574 and 634  $\text{cm}^{-1}$ , regarding the  $\text{MnO}_6$  octahedral double chains, along with some weak bands recorded at 287 and 505  $\text{cm}^{-1}$  [17]. Particularly, the low frequency Raman band at 183  $\text{cm}^{-1}$  has been assigned to an external vibration derived from the translational motion of the  $\text{MnO}_6$  octahedra and the Raman band at 386  $\text{cm}^{-1}$  has been attributed to the Mn-O bending vibrations. On the other hand, the bands at 574 and 634  $\text{cm}^{-1}$  are due to symmetrical Mn-O vibrations, being assigned to vibrations in the along direction of the  $\text{MnO}_6$  octahedral double chains, and in the perpendicular direction, respectively. Thus, the broadening, relative intensity and definition of the latter can be an indicative of the degree of development of the (2x2) tunnelled structure.

In the case of fresh CuO/Cryptomelane, the bands at 574 and 634  $\text{cm}^{-1}$  are not well defined, evidencing a poor crystallinity, as well as the relative intensities show a short length of nanofibers but a good definition of 2x2 channel size [15]. Attending to the used samples, the Raman spectra presents some differences between these bands in terms of Raman shift and relative intensities, which is consistent with changes in the crystalline periodicity of cryptomelane phase, and the connection between the  $\text{MnO}_6$  octahedra. In both cases, the band located at 634  $\text{cm}^{-1}$  is shifted towards lower wavenumber, up to 615  $\text{cm}^{-1}$ , which can be associated to a higher  $\text{Mn}^{3+}/\text{Mn}^{4+}$  ratio in the network formed by  $\text{MnO}_6$  octahedra [18,19]. Additionally, there can be discerned a shoulder at 655  $\text{cm}^{-1}$  in the CuO/Cryptomelane sample used in CO-PROX cycles in absence of  $\text{CO}_2$  +

H<sub>2</sub>O, that can be ascribed as the band characteristic for the symmetric stretching of Mn-O lattice for Mn<sub>3</sub>O<sub>4</sub> [20].

Thus, Raman characterization suggests that used samples are based on a distorted cryptomelane structure formed by MnO<sub>6</sub> octahedra whose manganese has in average a more reduced oxidation state compared to the fresh sample. The reduction of manganese in the cryptomelane structure is possible by means of the formation of O<sup>2-</sup> vacancies and/or by the insertion of a greater proportion of K species in the intratunnel space. However, such reduction cannot overcome certain boundaries due to the electrostatic repulsion of the hosted K species, which may provoke a segregation into Mn<sub>3</sub>O<sub>4</sub> and a K-enriched cryptomelane phases [10]. Comparing both used samples, Raman characterization evidences a higher development of Mn<sub>3</sub>O<sub>4</sub> phase in the sample used in absence of CO<sub>2</sub> and H<sub>2</sub>O in the catalytic tests.

In conclusion, the better performance of CuO/Cryptomelane catalyst after several CO-PROX experiments performed in the presence of CO<sub>2</sub> and H<sub>2</sub>O is related to its enhanced stability. In absence of CO<sub>2</sub> and H<sub>2</sub>O in the CO-PROX reaction feed, the catalyst is reduced leading to the formation of the phase Mn<sub>3</sub>O<sub>4</sub>, which decreases the catalytic activity up to a steady level. On the contrary, when CO<sub>2</sub> and H<sub>2</sub>O are present in the CO-PROX feed, their chemisorption maintains the tunnelled structure of cryptomelane.

## **6.4 Conclusions**

The catalytic activity of CuO/Cryptomelane for the preferential oxidation of CO in H<sub>2</sub>-rich streams has been studied in the absence and presence of H<sub>2</sub>O and CO<sub>2</sub>, and the following conclusions can be summarised:

- (1) For fresh CuO/cryptomelane catalyst, the presence of CO<sub>2</sub> and/or H<sub>2</sub>O in the CO-PROX feed partially inhibits CO oxidation due to chemisorption of H<sub>2</sub>O and CO<sub>2</sub> on the catalyst. H<sub>2</sub>O chemisorption on CuO/Cryptomelane is stronger than CO<sub>2</sub> chemisorption and simultaneous CO<sub>2</sub> and H<sub>2</sub>O feed has a synergetic effect that enhances co-adsorption.
- (2) On the contrary, the presence of CO<sub>2</sub> + H<sub>2</sub>O in the CO-PROX reaction mixture has a positive effect in the CuO/Cryptomelane stability upon several consecutive reaction cycles in the 25-200°C range.
- (3) XRD showed that CO<sub>2</sub> + H<sub>2</sub>O co-chemisorption partially prevents catalyst deactivation due to cryptomelane reduction to hausmannite (Mn<sub>3</sub>O<sub>4</sub>) under the strongly reductive environment of the CO-PROX reaction.
- (4) Additionally, H<sub>2</sub>-TPR and Raman spectroscopy characterization support that the cryptomelane structure is less damaged under CO-PROX conditions in the presence of CO<sub>2</sub> and H<sub>2</sub>O than in the absence of these species.

Therefore, this greater stability of CuO/Cryptomelane in realistic conditions (CO<sub>2</sub> and H<sub>2</sub>O presence) is eventually minimising the catalyst deactivation in CO-PROX reaction cycles and leads to the best catalytic performance after 4 cycles of reaction, which is a very interesting peculiarity of this material for the studied application.

# CHAPTER 7

## Into the Preferential Oxidation of CO reaction mechanism over CuO/Cryptomelane catalyst

CuO/Cryptomelane catalyst was subjected to a mechanistic study over CO-PROX reaction by means of indirect techniques by the preparation, advanced characterization and testing of catalysts with different Cu nominal contents. Their CO-PROX catalytic activity has been tested in CO-PROX reaction and evaluated according to Cu dispersion and synergistic interaction between copper and manganese-rich phases. This work entails the use of conventional characterization techniques such as XRD, Raman, XPS and Auger spectroscopies, as well as complementary basic DFT simulation. Additionally, it is reported for the first time, *in-situ* Work Function measurements over CO and O<sub>2</sub> interaction in CuO/Cryptomelane catalysts. Results reveal a strong influence in the electronic properties of CuO/Cryptomelane depending on CuO-cryptomelane interaction at the interface contact points, which stabilize Cu<sup>+</sup> states upon Cu<sup>+2</sup>/Cu<sup>+</sup> and Mn<sup>3+</sup>/Mn<sup>4+</sup> redox interplay. The optimal performance is achieved by the efficient participation of two active species: (1) interfacial Cu<sup>+</sup>-Mn pairs, as the active sites for CO oxidation; and (2) CuO bulky particles for the efficient O<sub>2</sub> refilling. Thus, these results bring the conclusion that clear analogies exist within the ongoing CO-PROX mechanism involving copper species in CuO/Cryptomelane and the well-reported CuO/CeO<sub>2</sub> catalysts.

## 7.1 Introduction

Along Chapters 5 and 6, a CuO/Cryptomelane catalyst was evaluated in CO-PROX reaction, and despite the moderate stability of the material in a continuous operation in reaction conditions, the activity of the CuO/Cryptomelane catalyst resulted very promising. Besides, provided its H<sub>2</sub>O and CO<sub>2</sub> compatibility, which turns into a major stability and activity maintenance in real CO-PROX operation conditions, CuO/Cryptomelane catalysts are truly interesting for practical reasons and a further study over particular mechanistic aspects is a must.

Hence, although CuO/Cryptomelane had already previously demonstrated an outstanding catalytic activity in CO-PROX reaction, mechanistic studies provided so far are truly limited when compared to CuO/CeO<sub>2</sub> catalysts [1–4]. Apart from the more extended use and the well-known excellent performance of CuO/CeO<sub>2</sub> materials in catalytic applications, which turn into a very large list of related reported literature, CuO/CeO<sub>2</sub> systems are more facile to analyse by means of conventional characterization techniques and the good track record provided brings a deep understanding of the ongoing mechanism [5,6]. In particular, *operando* CO-PROX DRIFT spectroscopy allowed to identify Cu<sup>+</sup> species as CO oxidation active sites, besides the enrolment of carbonaceous intermediate species, the role of OH surface groups, and the relevant Cu – Ce interfacial properties that determine Cu<sup>+</sup> carbonyl formation and stabilization [7].

In addition, along this Project Thesis the state-of-the-art into CuO/CeO<sub>2</sub> studies over CO-PROX reaction has been expanded by the novel *operando* NAP-XPS experiments complemented with in-situ Raman spectroscopy and Density Functional Theory calculations upon CeO<sub>2</sub> surfaces. It is complicated, tough, to stablish analogue analyses into CuO/Cryptomelane provided its great crystallographic complexity and mixed nature with potassium species and intra-channel bounded water on the MnO<sub>2</sub> network [8]. On the one hand, Mn XPS analyses are not trivial, given the many multiplet-split components of Mn2p peaks, which hinder substantially the interpretation of such region in the average spectra of Mn mixed species present in cryptomelane [9]. On the other hand, such complex crystallographic assembly in MnO<sub>6</sub> octahedra 2 x 2 channel arrays results in an entangled characteristic Raman spectra [10], from which it is difficult to retain critical information. And last, but not least, probably because of the characteristic black-colored nature of CuO/Cryptomelane catalyst, infrared spectroscopic *operando* CO-PROX analyses present flat spectra that do not allow to get mechanistic insights from this powerful technique [11].

In this scenario, some authors have reported a Mars van Krevelen (MVK) mechanism occurring when cryptomelane-based catalysts are used for oxidation reactions, such as in Volatile Organic Compounds (VOC) oxidation [12–14], or CO oxidation [11,15,16], based on indirect evidences such as O1s XPS region measurements or H<sub>2</sub>-TPR experiments. However,

to the best of my knowledge, the establishment of a proper CO-PROX reaction mechanism for the promising CuO/Cryptomelane formulation with *in-situ* techniques is still pending.

Therefore, the study presented along this Chapter deals with a proposed alternative methodology to study CO-PROX mechanism over CuO/Cryptomelane catalysts based on the multidisciplinary use of potential advanced complementary techniques. Namely, *in-situ* Work Function (WF) measurements were conducted [17], which offer a powerful tool and a novel approach for this mechanistic purpose. Additionally, the effect of Cu loading and CuO particle size has been critically included in the present Chapter.

## 7.2 Experimental details

### 7.2.1 Catalysts preparation

The synthesis of CuO/Cryptomelane was conducted according to procedure detailed in [Section 2.1.1](#) from Chapter 2. In this particular Chapter, a battery of CuO/Cryptomelane catalysts with different Cu loadings were prepared.

### 7.2.2 CO-PROX activity tests

The prepared CuO/Cryptomelane series was tested in CO-PROX catalytic tests according to the experimental settings and specific conditions as stated in [Section 2.2.3](#). Briefly, 100 ml/min of the CO-PROX gas mixture consisting in 2% CO, 2% O<sub>2</sub>, 30% H<sub>2</sub> in He balance ( $\lambda = 2$ ) was fed to the reactor with 150 mg of sample, and the experiment was conducted following heating rate of 2°C/min from 25 to 250°C.

### 7.2.3 Catalysts characterization

CuO/Cryptomelane catalysts were characterized by means of N<sub>2</sub> physisorption at -196°C, X-Ray Diffraction (XRD), Temperature Programmed Reduction with H<sub>2</sub> (H<sub>2</sub>-TPR), and X-ray photoelectron spectroscopy (XPS) analysis. Specific conditions of such measurements were detailed in [Section 2.2.2](#) from Chapter 2. Accordingly, surface area was calculated by using the BET equation ( $S_{\text{BET}}$ ), micropore volume (<2 nm) with the Dubinin-Radushkevich equation (DR), while Cryptomelane ( $\alpha$ -MnO<sub>2</sub>) crystallite size determined by means of the Scherrer equation considering the (211) peak.

Since cryptomelane is known to emit potassium at elevated temperatures [20,21], potassium thermal desorption was investigated by measuring the potassium atom flux from pelletized samples (100 mg, 13 mm diameter) heated in a vacuum chamber. Due to the low ionization potential of potassium ( $I = 4.3$  eV) from solid surfaces potassium is typically thermally

emitted in the form of atoms and ions. The samples were biased with a positive potential of +5 V to prevent the thermal emission of electrons during a heating program up to ~500 °C. For each temperature the resultant positive current was averaged over 10 independent data points and measure with the use of Keithley 6512 digital electrometer.

#### 7.2.4 *In-situ* Work Function measurements

Work function measurements were carried out under room conditions of atmosphere and temperature with the calcined and pelletized samples (6 MPa, 10 mm diameter). The contact potential difference (CPD) measurements were carried out by the dynamic condenser method of Kelvin with a KP6500 probe (McAllister Technical Services), and the reference electrode was a standard stainless-steel plate with a diameter of 3 mm ( $\Phi_{\text{ref}} = 4.3$  eV) provided by the manufacturer. During the measurements, the gradient of the peak-to-peak versus backing potential was set to 0.2 V, whereas the vibration frequency and amplitude was set to 120 Hz and 40 a.u. The final CPD value was an average of 60 independent points using two backing potentials. The work function values were obtained from a simple relation  $\text{CPD} = \Phi_{\text{ref}} - \Phi_{\text{sample}}$ . *In-situ* WF measurements over CuO/cryptomelane catalysts were conducted at 200 and 300°C after a thermal treatment up to 450 °C in vacuum conditions. The atmosphere was switched among vacuum (below  $10^{-6}$  atm), O<sub>2</sub> (Air Products, 99.9998%) and 5% CO/He at two different chamber pressures:  $3.5 \cdot 10^{-5}$  and  $8.0 \cdot 10^{-5}$  atm.

#### 7.2.5 Density Functional Theory (DFT) Calculations

DFT calculations were conducted by means of the CP2K package in its 4.1 version using the QUICKSTEP module [49]. Dispersion corrected (D3)[50] GGA-PBE[51] exchange correlation functional under periodic boundary conditions (PBS) were used for all simulations. CO and H<sub>2</sub> molecules were positioned close the surface of Cu(111), Cu<sub>2</sub>O(111) and CuO(111) slabs of 320 atoms, 180 atoms and 160 atoms respectively and the systems were allowed to relax. Adsorption energies were calculated by using the equations:

$$E_{\text{CO,ads}} = E_{\text{slab} + \text{CO,ads}} - (E_{\text{slab}} + E_{\text{CO(g)}})$$

$$E_{\text{H2,ads}} = E_{\text{slab} + \text{H2,ads}} - (E_{\text{slab}} + E_{\text{H2(g)}})$$

Additional information on the computational approach can be found in [Section 2.3](#) from Chapter 2.

## 7.3 Results and discussion

### 7.3.1 Catalyst characterization

Textural, crystallographic and chemical characterization results for Cryptomelane and CuO/Cryptomelane catalysts are presented in Table 7.1, as a screening of Cu loading effect towards the physicochemical features and catalytic activity. The nominal Cu content was determined by means of XRF, and this result provided the denomination for each CuO/Cryptomelane catalyst, namely: 4% CuO/Cryptomelane, 7% CuO/Cryptomelane and 11% of CuO/Cryptomelane loading, which, for the sake of simplicity, are named henceforward in the present Chapter as 4% Cu/CR, 7% Cu/CR and 11% of Cu/CR, respectively.

**Table 7.1.** Compiled results of characterization by N<sub>2</sub> adsorption, XRF (bulk) and XPS (surface) quantification.

Catalyst	S <sub>BET</sub> (m <sup>2</sup> /g)	V <sub>DR</sub> (cm <sup>3</sup> /g)	<sup>(a)</sup> wt.% Cu	<sup>(a)</sup> Cu/Mn	<sup>(b)</sup> % C	<sup>(b)</sup> Cu/M
CR	72	0.041	-	0.000	42	0.000
4% Cu/CR	63	0.034	3.7	0.036	29	0.403
7% Cu/CR	56	0.034	7.2	0.073	30	0.677
11% Cu/CR	55	0.033	11.2	0.118	31	0.830

<sup>(a)</sup>From XRF characterization; <sup>(b)</sup>From XPS analysis.

On the other hand, the calculated BET surface of the catalysts decreases by increasing Cu content, whereas the micropore volume (V<sub>DR</sub>) is lowered in a constant degree for all Cu/CR catalysts. Since N<sub>2</sub> physisorption technique is limited at providing information in the ultra micro-pore range (< 0.7 nm), as in the case of cryptomelane tunnel size (0.65 nm diameter), the micropore volume determined does not consider intra-channel space [22]. Thus, textural results reveal that Cu lowers cryptomelane specific surface by porosity blocking upon CuO deposition, although partial tunnel insertion or framework substitution cannot be ruled out.

The chemical quantification by XRF analysis reveals real Cu content in the Cu/CR catalysts, whereas XPS shows surface composition. Considering the equivalent atomic Cu/Mn bulk ratios, this parameter shows a proportional linear trend upon Cu loading. On the contrary, analogue atom ratios provided by XPS analysis showed surface Cu enrichment in all cases. Furthermore, among the Cu/CR catalysts, Cu surface content is not monotonically coupled to Cu nominal values. This deviation suggests the formation of larger CuO particles by copper sintering as Cu loading increases. This effect is identified by XPS as a lowering in the Cu content. On the other hand, surface % C decreases in Cu/CR samples with respect to CR, which is a reported side-

effect of the impregnation with acid copper precursor solution based on structural and surface carbonate dissolution [23].

XRD characterization (Figure 7.1) showed a pattern for all the catalysts consisting of the characteristic diffraction peaks of cryptomelane (JCPDS no. 29-1020). The presence of CuO tenorite phase (JCPDS no. 80-1268) is only detected in 11% Cu/CR catalyst, which is indicating that in lower contents, CuO may be highly dispersed, and its crystallite size is below the threshold detection limit of the XRD apparatus. On the other hand, important crystallite size changes upon Cu loading on bare cryptomelane phase were discarded by means of calculations using the Scherrer equation and lattice parameters considering tetragonal phase (Table 2.2) [24,25].

**Figure 7.1.** X-Ray diffractograms for CR and Cu/CR catalysts with peak markers for characteristic diffraction patterns of cryptomelane (‡) and CuO (\*) structures.

**Table 2.2.** Crystallite size and cryptomelane lattice dimensions by XRD using (211) and (310) diffraction peaks.

Catalyst	$D_{\text{Scherrer}}$ (nm)	Lattice constant "a" (nm)	Lattice constant "c" (nm)	Cell volume (Å <sup>3</sup> )
CR	22	0.9811	0.2403	231
4% Cu/CR	23	0.9828	0.2400	232
7% Cu/CR	27	0.9811	0.2397	231
11% Cu/CR	24	0.9795	0.2397	230

In conclusion, Cu loading is not altering the basic  $\text{MnO}_x$  framework structure of cryptomelane, in agreement with the expected low degree of Cu lattice insertion by following an impregnation procedure. The decrease in

BET surface should be attributed to the formation of CuO particles deposited mainly on the external surface of cryptomelane that partially block the porosity. The higher the Cu content, the larger the CuO particle size, which is detected as a crystalline phase in 11% Cu/CR. Thus, according to these results, it may be inferred that 4% Cu/CR presents the higher Cu dispersion, 7% Cu/CR should be composed of medium-sized particles with good dispersion, too, and finally in 11% Cu/CR CuO presents the largest particle size with lower dispersion.

### 7.3.2 CO-PROX catalytic activity tests

Bare cryptomelane (CR), bulk CuO and the prepared CuO/Cryptomelane (Cu/CR) catalysts were tested in CO-PROX reaction activity experiments and results are presented in Figure 7.2.

**Figure 7.2.** (a) CO conversion; and (b) CO selectivity profiles in CO-PROX activity tests conducted with the prepared catalysts. 150 mg, 2 °C/min, 100 ml/min 2% CO, 2% O<sub>2</sub>, 30% H<sub>2</sub> balance He.

The beneficial effect of Cu loading into cryptomelane in the Cu/CR catalysts performance with regards to bare CR and CuO samples is clear and evidenced by a dramatic lowering in the temperature range over CO conversion profiles, roughly shifted ca. 100°C lower for Cu/CR catalysts. Such enhancement, reported elsewhere, is attributed to the synergistic effect between MnO<sub>x</sub> from cryptomelane (CR) and CuO phases, which brings about a large increase of lattice oxygen mobility, as a result of the formation of Cu-O-Mn bridges which partially delocalize electron density in Mn-O bonds [26–28]. Furthermore, the labile redox interplay Cu<sup>2+</sup>/Cu<sup>+</sup> on the reducible MnO<sub>x</sub> surface promotes the creation of defects such as oxygen vacancies in the cryptomelane framework via Mn<sup>2+</sup> substitution in the interface points. Hence, the presence of such defects increases the lattice oxygen activation and reactivity [12,29] which may accelerate CO oxidation rate occurring by means of Mars-van Krevelen (MVK) mechanism with the participation of surface oxygen [30].

According to MVK mechanism, lattice oxygen is directly involved in the oxidation process of chemisorbed CO species, and, as a result, oxygen vacancies are created upon the reaction course. Those oxygen vacancy defects are replenished by O<sub>2</sub> gas dissociation and incorporation in balanced equilibria, keeping stable the average oxidation state of the catalyst. In the case of Cryptomelane catalyst, CO oxidation should take place upon the labile redox Mn<sup>3+</sup>/Mn<sup>4+</sup> interplay, whereas in CuO/Cryptomelane catalysts, CuO can additionally undergo analogue redox processes involving partial reduction to state Cu(I). Attending to this, since CuO presents large stability on its oxidized state, which facilitates lattice oxygen recovery, besides an enhanced CO chemisorption capacity, it could be inferred that processes attained to CuO participation is more favourable for the achievement of higher CO oxidation rates. However, provided the catalytic testing of pure CuO presents negligible CO oxidation activity in the temperature threshold of interest, catalytic activity of CuO phase is only relevant when dispersed on a MnO<sub>x</sub> surface in CuO/Cryptomelane samples. As a result, a synergistic effect between CuO – Cryptomelane contact points at the interface should be activating the oxygen lattice evolution in both phases, as stated before. Thus, the changes of catalyst features such as CuO dispersion, particle size and distribution in the cryptomelane support are expected to have large effects on the catalytic activity.

Conversely, the differences are moderate among the series of CuO/Cryptomelane catalysts, which reach the maximum CO conversion (~90 %) in a narrow temperature range, following the trend 7% Cu/CR > 11% Cu/CR > 4% Cu/CR. Nevertheless, in terms of CO selectivity, 7% Cu/CR and 11% Cu/CR catalysts present the best behavior with region of complete CO selectivity at low temperatures and the typical selectivity decay up to (~40 %), by the competitive H<sub>2</sub> oxidation on-set. Such selectivity value is acceptable to guarantee a good CO-PROX catalytic performance, provided the experimental conditions of λ=2 for O<sub>2</sub> [31]. Therefore, 7% Cu is assessed

as the optimum loading in Cu/CR catalysts, but in close similarity to the 4 and 11%. As a result, 7% Cu/CR catalyst, with an inferred intermediate CuO particle size, presents the preferential chemical features. In order to get further insights regarding those optimum properties in terms of CuO – CR interactions and redox properties of CuO/Cryptomelane catalysts, H<sub>2</sub>-TPR and XPS analysis were conducted.

### 7.3.3 CuO – Cryptomelane redox interaction study

Figure 7.3 displays the H<sub>2</sub>-temperature programmed reduction profiles of the tested catalysts, showing that their different susceptibility for H<sub>2</sub> reduction is affected by the interaction of C and CuO phases.

**Figure 7.3.** H<sub>2</sub>-Temperature Programmed Reduction profiles of Cryptomelane, CuO/Cryptomelane and CuO catalysts.

In the case of cryptomelane phase, manganese species achieve the final oxidation state of +2 under the reduction treatment [32–34]. For pure

cryptomelane, CR profile presents three main reduction events assigned to the redox processes: (i)  $\text{MnO}_2 \rightarrow \text{Mn}_2\text{O}_3$ ; (ii)  $\text{Mn}_2\text{O}_3 \rightarrow \text{Mn}_3\text{O}_4$ ; and (iii)  $\text{Mn}_3\text{O}_4 \rightarrow \text{MnO}$ , seen in broad peaks centred at 300, 335 and 350°C, respectively [28,29]. The introduction of 4% Cu produces little changes in the average reduction of cryptomelane framework, presenting an overlapping of the manganese reduction processes occurring in the same temperature range as in bare CR. Nevertheless, an extra peak at 150°C assigned to finely dispersed CuO species is detected in the reduction profile. Since reduction of pure bulk CuO occurs above 300°C according to the  $\text{H}_2$ -TPR profile of CuO sample, also shown in Figure 7.3, this anticipated CuO reduction evidences a Cu – Mn synergistic effect by means of the formation of labile  $\text{Cu}^{2+} - \text{O} - \text{Mn}^{y+}$  entities [35–37]. As a consequence, the anticipated partial  $\text{MnO}_2$  reduction is gradually taking place as well, evidenced by the permanent sloping signal above 150°C after small size CuO particles reduction. In contrast, the effect of Cu is much more evident in the 7 and 11% Cu/CR catalysts by shifting the maxima towards lower temperatures of the overall cryptomelane reduction processes (from 350 to 330°C). This shifting proves the superior Cu – Mn interaction in 7% Cu/CR and 11% Cu/CR catalysts, and the effective promotion of  $\text{Mn}^{4+}/\text{Mn}^{3+}$  redox interplay. The reduction peak attributed to the anticipated reduction of CuO disperse particles is also observed. The 7% Cu/CR catalyst displays the greatest area and peak definition, while in 11% Cu/CR, a hindered reduction and limited Cu – Mn contact by the larger CuO particles can be observed, since bulky CuO reduction may be overlapping with  $\text{MnO}_x$  reduction processes at higher temperatures. Furthermore, the broadening of the reduction profile and the appearance of an anticipated manganese reduction peak centred at 250°C evidences the more labile manganese redox properties in 7% Cu/CR catalyst than in the other two Cu/CR catalysts.

Figure 7.4a, shows that  $\text{Cu}2p\ 3/2$  spectra are broad and composed of multiple copper species with two main contributions, the first at lower binding energy (931.5 – 932.0 eV), and the second higher binding energy (933.6 – 933.8 eV). On the other hand, although overlapped under Mn LMM lines characteristic Cu(II) satellite peaks are observed in all cases.

**Figure 7.4.** (a) Deconvoluted XPS  $\text{Cu}2p_{3/2}$  photoemission region. (b)  $\text{Cu L}_{3}\text{M}_{4.5}\text{M}_{4.5}$  Auger spectra of CuO and Cu/CR prepared catalysts

The detailed analysis of XPS and Auger spectra for CuO and Cu/CR catalysts, presented, allows to conclude that  $\text{Cu}^{2+}$  is the main copper species present, although two different electronic environments are found and assigned to: (i) the higher BE contribution:  $\text{Cu}^{2+}$  species belonging to CuO particles (ii) the lower BE contribution:  $\text{Cu}^{2+}$  in intimate contact with the support and enhanced reducibility by means of  $\text{Cu}^{2+} - \text{O} - \text{Mn}^{y+}$  bridges. The abundance relation between both type of species is tentatively associated to the degree of copper oxide – cryptomelane interaction, which results significantly higher in the case of 4% Cu/CR, when compared to 7 and 11% catalysts (Table 7.3). Likewise, 4% Cu/CR catalyst presents the highest percentage of reducible copper, which is a sign that evidences the stronger CuO-CR interaction [40].

**Table 7.3.** Modified Auger parameter and Cu distribution percentages for Cu/CR catalysts based on XPS and Auger characterization. [\*] Using for calculation main 2p contribution.

Catalyst	$\alpha'$ (eV) [*]	% Cu(I) + % Cu(0)	% Cu <sup>2+</sup>
4% Cu/CR	1850.7	39	61
7% Cu/CR	1851.1	29	71
11% Cu/CR	1851.2	22	78

On the other hand, neither Mn 2p region nor O1s region analyses (not shown results) presented have shown significative differences in the Mn average oxidation state (AOS) or in the oxygen species in the CR and Cu/CR catalysts. These results are in contrast with other authors' who reported an increased Mn AOS in cryptomelane by Cu substitution or deposition [11,32,42], as well as a greater population of loosely bound oxygen species [28,42]. Therefore, unfortunately we cannot confirm by this technique the effect of copper at the promotion of Mn redox properties in the Cu/CR catalysts, but conversely, the presence of Cu species with a more negative electron environment following the trend 11% Cu/CR < 7% Cu/CR < 4% Cu/CR can be an evidence of the CuO-CR interaction.

To get further insights, work function (WF) measurements of the Cryptomelane and Cu/Cryptomelane catalysts and a CuO reference were conducted, and the results are presented in Figure 7.5a. This technique provides information about the energy required to extract electrons from the solids, and the lower WF of a material indicates higher electron availability, which leads to a higher reactivity of such catalysts in the reactions where electron transfer from the catalyst surface to reacting molecule plays a key role [43]. The compiled data are consistent and show close values for bare cryptomelane (CR) and copper oxide(II), which hinders to establish a simple correlation among the series of Cu/CR prepared catalysts. Nevertheless, it is clearly observed a decrease in work function for 7% Cu/CR catalyst, even when compared to both pure phases CuO and Cryptomelane, which is an evidence of electrodonor properties in this sample because of a promoted Cu-Mn interaction. Thus, a lower work function value could be roughly associated to the higher facility towards reduction of the material and in this case 7% Cu/CR presents the strongest effect, in-line with the H<sub>2</sub>-TPR results.

**Figure 7.5. (a)** Work Function ( $\Phi$ ) measurements of CR, Cu/CR prepared samples and CuO reference (100% Cu in X-axis) in air and room temperature conditions. **(b)** Temperature for  $200 \mu\text{mol CO/s} \cdot \text{g}$  of reaction rate plotted against Work Function differences ( $\Delta\Phi = \Phi_{\text{Cu/CR}} - \Phi_{\text{CR}}$ ) by the effect of copper loading.

Nevertheless, taking into account the conditions of the measurements, and the prior state of samples after calcination in air, the presence of chemisorbed carbonates, hydroxyls and surface groups is important and its effect in work function values should not be ruled out. This surface chemistry affects the electrical properties by the formation of diffuse surface dipoles and electron density transference, which is evidenced by a work function lowering [44,45]. Thus, the behavior observed with regard to work function is representative of the abundance of oxygen surface species, which are present at the beginning of the CO-PROX activity experiments, as well. These oxygen containing groups (carbonates, bicarbonates, formates and hydroxyls) are not only spectators, but also take part in the CO-PROX mechanism suggested elsewhere [7]. Therefore, for 7% Cu/CR catalyst, which presents the lowest work function value, it can be inferred that the maximum degree of electronic surface distortion with atmospheric

components occurs, matching its better catalytic performance. In this regard, Figure 7.5b shows the work function decrease of Cu/CR catalysts compared to bare cryptomelane and its correlation with the reaction rate at low CO conversion by means of the characteristic temperature for 200  $\mu\text{mol CO/s} \cdot \text{g}$  in CO-PROX experiment.

The trend is clear, showing that reaction rate is accelerated with the lowering of the catalyst work function, establishing eventually a plateau below 0.1 eV of decrease. Thus, according to CuO – Cryptomelane interaction quantified by means of work function decrease, 7% Cu/CR catalyst presents the strongest synergistic effect towards reduction and oxygen groups chemisorption, which should be related to the presence of randomly dispersed CuO particles.

#### **7.3.4 Role of K in CuO – CR interaction**

One key factor for the understanding of the great activity of cryptomelane-based catalysts is the role of potassium in the electronic promotion of copper and manganese towards reduction and oxygen donor capacity. In this regard, specific analysis techniques have been performed in order to establish appropriate determination of such properties. First of all, XPS analysis of K2p photoemission region presented in Figure 7.6, confirms there are no significant differences among potassium electronic states in the prepared catalysts, as deviations in peak maxima are below XPS sensitivity threshold (0.2 eV), in the 2p<sub>3/2</sub> peaks centred, on average, at ca. 291.5 eV, which are values reported for cryptomelane [46]. Comparing with ionic potassium compounds, which present a sharp peak centred at 292.9 eV [47], such particularly low BE results are an evidence of potassium electronic enrichment by MnO<sub>x</sub> donation in the narrow confinement inside cryptomelane tunnels. Thus, as this BE shifting is present in all Cryptomelane-based catalysts, it can be concluded that K electronic density is not dependent on copper content, showing that most probably copper and potassium are not directly interacting electronically.

**Figure 7.6.** XPS K2p photoemission region for CR and Cu/CR prepared catalysts.

Additionally, the stability of potassium species was studied by thermal desorption tests, measuring the potassium atom flux from the samples heated in a vacuum chamber (Figure 7.7). Potassium thermal desorption measurements reveal that the process takes place over 400 °C, thus at temperatures much higher than the CO-PROX catalytic activity. The linear part in the Arrhenius' plot corresponds to typical activation barriers for desorption of 2.1 eV without significant differences for CR and 7% Cu/CR catalysts. It means that the structure of cryptomelane, and thus the state of potassium, is not altered by the addition of copper oxide particles.

**Figure 7.7.** Potassium desorption as a function of temperature for **(a)** CR and **(b)** 7% Cu/CR catalyst.

In conclusion, potassium species play essentially a structural role in Cu/CR catalysts, stabilizing cryptomelane tunnels via electronic interaction with  $\text{MnO}_6$  octahedra. Conversely, there is not an electronic promotion or activation of the dispersed copper oxide particles upon K interaction, which is not an unexpected conclusion since potassium remains inside the tunnels, whereas CuO is located at the periphery covering the external surface of cryptomelane. Therefore, since K – CuO interaction is scarce and occurs only by means of  $\text{MnO}_x$  intermediation, the particular contribution of K species in the catalytic activity should be equivalent for Cryptomelane and CuO/Cryptomelane catalysts, for which is not further considered in the present discussion.

### 7.3.5 Study of $\text{CO}/\text{H}_2$ interaction with Cu/CR catalysts

Since it is truly complex to obtain mechanistic data for CuO/Cryptomelane catalysts when compared to other studied catalysts,

such as ceria-based ones, with a thorough studies of well-known interpretation [5,7], in order to get analogue mechanistic information for cryptomelane-based catalysts, instrumental and methodological alternatives must be considered.

#### 7.3.5.1 Density Functional Theory (DFT) calculations

Simple DFT calculations for the energy of adsorption of CO and H<sub>2</sub> gas molecules onto copper substrates in different oxidation states were conducted. Thus, the aim of this study is to discern the adsorption affinities of CO and H<sub>2</sub> at the different copper-based structures, representative of the catalyst state during reaction course.

Figure 7.8 compiles adsorption energies for CO and H<sub>2</sub> gas molecules onto copper-based slabs in their most favourable cases, considering dissociative or non-dissociative adsorption at different surface sites (Figure 7.9a-f).

**Figure 7.8.** Energy of adsorption (eV) for CO and H<sub>2</sub> gas molecules onto slabs of CuO, Cu<sub>2</sub>O and Cu, respectively.

**Figure 7.9.** (a,b) CuO(111), (c,d) Cu<sub>2</sub>O(111) and (e,f) Cu(111) surface slabs in the most favourable interaction with (a,c,e) CO; (b,d,f) H<sub>2</sub>.

By the assumption that adsorption of gas molecules on the surface of the active sites is the first key step for catalytic reaction to occur, the difference between the energetics of these processes can be tentatively related to the CO-PROX selectivity for each copper-based surface. Therefore, by simple subtraction, it can be established that Cu(I) surface presents the highest energy difference for CO and H<sub>2</sub> adsorption, so the best selectivity is achieved when copper is partially reduced.

When it comes to the whole data comparison, Figure 6 shows that for CuO, initial state of the catalyst, the adsorption of H<sub>2</sub> presents quite low energy, whereas CO is significantly higher. In this case, CO-PROX reaction is based on a truly selective CO oxidation. Such activity is enlarged when CuO is partially reduced to Cu<sub>2</sub>O, as energy of adsorption rises from -1.30 to -2.10 eV. In the same way, the surface doubles the affinity for H<sub>2</sub> adsorption, going from -0.31 eV for Cu(II) to -0.68 eV for the Cu(I) surface. This change can be related with the onset of H<sub>2</sub> oxidation reaction and therefore a loss in selectivity loss from the maximum values. Finally, when Cu<sub>2</sub>O is reduced to Cu, the difference between energies of adsorption of CO and H<sub>2</sub> notably decreases, which is may be the cause of poor selectivity and a strong competition.

Despite the fact that the description of adsorption energetics profile matches that of experimental data, it must be taken into account that not all adsorption interactions are necessarily translated into chemical reaction, as a high percentage of adsorptive processes are not efficient and eventually lead to desorption in an adsorption-desorption pseudo-equilibrium situation. However, the energy of adsorption can be an indicator of average reaction process taking place as the relative population of CO and H<sub>2</sub> coverage is

affected, and then, the probability of reaction. Furthermore, the higher coverage of CO and H<sub>2</sub> is blocking the adsorption of their counterpart, as competitive adsorption is assumed according to this model.

In this environment, considering that the support MnO<sub>x</sub> is stabilizing the Cu(I) particles by means of Cu-Mn synergistic interaction on CuO – MnO<sub>x</sub> interface, it can be concluded that the best activity is obtained when the catalyst maximizes Cu – Mn interaction. As it was described before along the manuscript, this interaction is the strongest for 7% Cu/CR, according to H<sub>2</sub>-TPR analysis and work function measurements. On the other hand, despite for 4% Cu/CR catalyst, Cu – Mn interface is maximized and copper species present a partially reduced state up to a higher extent, synergy at Cu and Mn reducibility is not clearly observed. Therefore, it is the cyclability of redox processes between Cu(II)/Cu(I) the driving force that induces the best catalytic performance, as lattice oxygen is actively participating in the reaction mechanism. So, for the lowest Cu loading (4%), CuO particles are too small to stabilize Cu(II)/Cu(I) mixed states, conceived as bulky CuO particles with surface reduction.

#### 7.3.5.2 In-situ Work Function measurements

Thus, in order to check reactivity of Cu – Mn interfaces, *in-situ* work function measurements in an evacuated chamber with further addition of O<sub>2</sub> or CO gases were conducted to check WF changes in those atmospheres. WF is a highly sensitive surface reactivity descriptor and a useful measurable parameter, as it is claimed that surfaces undergo work function changes upon interaction with selected gases according to different sensing/reaction schemes [17,48]. In the case of semiconducting materials, the strength of interaction is directly reflected in WF change, assigned to the depletion/restitution of electrons from the conduction band (CB). The effect can be discussed in terms of the interaction of probe molecules with the surface: (1) O<sub>2</sub>, by O<sup>-</sup> ionosorption (Equation 7.1); and (2) CO, by surface reduction (Equation 7.2), as particular cases for CO sensing materials. The description of these processes can be done according to the following scheme, where S represents surface sites [17,49,50]:

Equations 7.1 and 7.2 suggest that atmospheric oxygen thermally dissociates at the semiconducting sensor surface and is adsorbed as atomic ions by trapping conduction electrons. On the other hand, reducing gases, such as CO can undergo catalytic oxidation removing the ad-oxygen and releasing the captured electron back into the CB. Process from (1) leads to a work function rise as oxygen concentration yields surface negative charge, enlarging surface barrier and depletion degree. Whereas process (2) is generally observed as a weaker interaction consuming partially adsorbed/surface oxygen and releasing some captured electrons in the CB,

providing a slight work function lowering, since CB electrons do not influence directly into work function of the material, but its conductivity.

Therefore, WF measurements under  $O_2$  and CO atmospheres at temperatures at which the catalysts present activity towards CO oxidation, can provide valuable information about catalyst – adsorbate interaction. In order to conduct these analyses, the measurement chamber was heated to 200°C and the studied gasses were added to increase the total pressure in two steps, using: (1) bare cryptomelane; (2) 7% CuO/cryptomelane; and (3) pure CuO; which are representative for  $MnO_x$  surface; Cu – Mn interface and CuO surface; respectively. Figure 7.10 compiles these results.

**Figure 7.10.** WF differences ( $\Delta\Phi = \Phi_{p,i} - \Phi_{vac}$ ) measured at 200°C by the effect of (a)  $O_2$ ; (b) CO, on clean pretreated surfaces (500°C, 30 min vacuum) of cryptomelane (CR), 7% CuO/cryptomelane (7% Cu/CR) and pure CuO.

Figures 7.10a and 7.10b evidence important differences in the behavior of the tested samples, as well as between interacting probe molecules. When it comes to  $O_2$  interaction, WF rises with  $O_2$  concentration in the chamber, as previously explained, according to the theoretical model.

In all cases, this interaction is mainly non-reversible, as vacuum measurement after O<sub>2</sub> contact does not bring back original work function values. Comparing between samples, 7% Cu/CR and CuO show a sharp work function change upon O<sub>2</sub> interaction, while CR shows much poorer response. These results reveal that the copper-rich phase is active for O<sub>2</sub> ionosorption and lattice oxygen vacancy replacement, but not MnO<sub>x</sub>. However, CuO – CR contact phases occurring at 7% Cu/CR catalyst maximizes O<sub>2</sub> interaction, and therefore, oxygen restitution during reaction. It has to be taken into account that prior to analysis, samples were pretreated at 450°C for 30 min in vacuum, which generally produce structural oxygen release and partial reduction, from CuO to CuO<sub>1-δ</sub> and MnO<sub>x</sub> to MnO<sub>x-δ</sub>. Thus, the great ability of CuO to undergo easy reduction when compared to MnO<sub>x</sub> makes it more susceptible to accept oxygen species from the gas phase, which is observed by a large work function change response. However, it occurs at a higher extent in the case of 7% Cu/CR sample, where a synergistic effect is clearly promoting oxygen restoration in the catalyst. In a possible mechanism, partially reduced CuO<sub>1-δ</sub> particles would act as O<sub>2</sub> caption sites, facilitating then, by a spillover effect at the interface, their transport towards MnO<sub>x</sub>, and releasing again CuO<sub>1-δ</sub> sites for new coming O<sub>2</sub> molecules. Thus, changes are more significant in Cu/CR as MnO<sub>x</sub> takes part as oxygen receptor as well, increasing average oxygen capacity. Besides, given the promoted reduction of MnO<sub>x</sub> and CuO in 7% Cu/CR catalyst, it is rational to expect higher extent in vacancy formation, leading to a higher oxygen uptake, and then, a larger work function change.

Regarding Figure 7.10b, a negative change in work function is observed by the effect of CO – surface interaction, assigned to the release of an electron into the CB as a product of CO oxidation, and removal of surface oxygen dipoles. Taking into account that the temperature of measurement is 200°C in chamber (~150°C on sample surface), this modification should necessarily be related to the catalyst activity in CO oxidation at such range of temperatures: 7% Cu/CR (~90% conv. CO) >> CR (~10% conv. CO) > CuO (~2% conv. CO). Despite the fact that the changes are much weaker when compared to O<sub>2</sub> measurements, the trend observed is clear, showing that for 7% Cu/CR the interaction is the strongest, whereas for reference CuO the electron affinity is not modified. Another important fact which is observable on Figure 7.10b is the non-reversible CO electronic effect, observed by a maintenance or even slight increase in work function modification after chamber evacuation back to vacuum, which is rather expected as the effect is related to chemical reaction and not merely an adsorption process.

**Figure 7.11.** Work Function differences ( $\Delta\Phi = \Phi_{p,i} - \Phi_{vac}$ ) measured at 200 °C over 7% Cu/CR catalyst by the effect of switching atmospheres (i) pO<sub>2</sub>: 8·10<sup>-5</sup> mbar, for 30 minutes; (ii) p CO: 4·10<sup>-6</sup> mbar, for 60 minutes, following the sequence: **(a)** O<sub>2</sub>-CO-O<sub>2</sub>; **(b)** CO-O<sub>2</sub>-CO.

Finally, as complementary characterization using Kelvin Probe instrument, *in-situ* work function measurement experiments with switching O<sub>2</sub>/CO atmospheres were conducted on 7% Cu/CR catalyst, results of which are presented in Figure 7.11.

The conducted gas switching experiments reveal that the presence of O<sub>2</sub> prevails over CO due to stronger interaction with the surface of the catalysts in the initial uptake, even though the pressure gap between O<sub>2</sub> and CO steps has been compensated by a longer CO exposure. Independent of whether O<sub>2</sub> or CO is supplied first, according to Figure 9a,b on average their introduction conduces to an increase of +0.13 eV, and decrease of -0.02 eV, respectively, in a quite good cyclability. Additionally, turning back to vacuum does not recover in any case work function values from the beginning, probing the non-reversible effect of such gas-surface interaction as described above. Whereas O<sub>2</sub> is refilling vacancies and abstracting electrons from CB, CO is providing electrons to CB and removing lattice O<sub>2</sub><sup>-</sup>, back and forth in an imbalanced cycle with superior O<sub>2</sub> interaction. So, as a final remark, lattice oxygen must be necessarily involved in CO oxidation mechanism according to MVK mechanism.

Compiling these data, it must be concluded that it is in CuO/Cryptomelane where both O<sub>2</sub> ionosorption and CO oxidation are maximised, ultimately observed by means of a greater catalytic activity. In the case of Cryptomelane, despite presenting interaction with CO, O<sub>2</sub> restoration is a severe limiting step towards restitution of active oxygen to participate in CO oxidation reaction, thus presenting poor catalytic activity. In this sense, copper-rich phase aids O<sub>2</sub> storage and release in CuO/Cryptomelane catalyst, skipping such barrier with a good Cu – Mn interaction under tight contact of both constituent phases. On the other hand, on CuO<sub>x</sub> surface, CO interaction is not observed as work function change, but given the nature of electron transference is based on CO oxidation process, CO chemisorption cannot be ruled out. In fact, according to DFT calculations on CuO<sub>x</sub> surfaces, it is predicted a strong CO chemisorption, however, without the appropriate oxygen assistance supply in absence of O<sub>2</sub> at the atmosphere, this CO sorption does not lead to effective catalytic activity in the oxygen-poor pure CuO<sub>x</sub>.

It can therefore be concluded that cryptomelane would act as an oxygen restitution reservoir towards CuO, stabilizing partially reduced particles at the Cu – Mn interface, enabling CO oxidation to take place. It is, thus a solid evidence of the role of active interface points between MnO<sub>x</sub> and CuO dispersed clusters in Cu/CR type catalysts in CO oxidation reaction, as well as a proof of Mars van Krevelen mechanism.

## **7.4 General discussion**

From the Cu/CR prepared catalysts, 7% Cu/CR resulted the optimum and the characterization of this material revealed that it is constituted by well dispersed CuO particles on the cryptomelane support, leading to a good Cu – Mn interaction. The Cu – Mn interaction was observed by means of an enhanced reducibility when compared to separate MnO<sub>x</sub> and CuO materials.

The strong effect of copper loading into CO-PROX activity performance was attributed to the gain in CO / O<sub>2</sub> interaction with the catalytic surface on the Cu – O – Mn sites, which promotes Cu(I) states with the predicted maximum selective CO chemisorption compared to that of H<sub>2</sub>. The synergistic Cu – Mn effect relies on the labile oxygen transference and replacement from O<sub>2</sub> phase, crucial in MVK mechanism oxidation reactions. On the one hand, CR shows a measurable CO interaction, but O recovery is not efficient, while CuO, which is prone to reoxidation with O<sub>2</sub>, and chemisorbs CO with no changes in WF. The synergism found in Cu/CR catalysts allow us to predict the reaction mechanism for CO oxidation, represented by the following scheme:

First, CO oxidation takes place in the interfacial O from CuO – MnO<sub>x</sub> (Step 1) since the redox interaction of Cu – Mn bonding provides an extra charge density in Cu<sup>2+</sup> species, which present the highest CO chemisorption energy. Secondly, the O vacancy created upon CO oxidation, could be immediately refilled by O<sub>2</sub> gas (Step 2a), recovering its initial state, or alternatively, the active Cu<sup>+</sup> formed could oxidize another CO molecule, achieving a more reduced state by the formation of another oxygen vacancy (Step 2b). The catalyst would undergo one pathway or another depending on the temperature. Presumably at lower temperatures, Step 2a would prevail over Step 2b, while at higher temperatures of reaction in CO-PROX conditions, Step 2b would be faster, keeping the catalyst in a reduced state. Then, with ambient oxygen, the catalyst recovers a partially oxidized state (Step 3b), and it is predicted that the first oxygen vacancy to be refilled may be the one located at the Cu – Mn interface, since it was proven that O<sub>2</sub> interaction was maximised for Cu/CR catalyst when compared to pure CuO sample.

Finally, the catalysts could undergo a further CO oxidation step with interfacial oxygen, or promote its transference towards the Cu-rich phase to recover partially recover the Cu(II) oxidized state (Step 4b) and ultimately produce again CO oxidation. Since it was checked that in 7% and 11% Cu/CR catalysts Mn reducibility was improved, it is expected that this process gains importance when CuO particles are larger, ensuring the formation of stable CuO bulky sites. Anyhow, both lattice oxygen sites (interfacial and from the CuO bulk) should present good CO oxidation capacity, and specially at high temperatures the accelerated reaction rate would make both sites indistinguishable.

## 7.5 Conclusions

The CO-PROX reaction mechanism has been studied for CuO/Cryptomelane catalysts and it has been disentangled the individual role of CuO particles and the cryptomelane support, as well as the synergistic effect of the active Cu – Mn interface. The main conclusions achieved may be summarized as follows:

(1) When Cu is deposited in a cryptomelane substrate for the preparation of CuO/Cryptomelane catalysts, it mainly forms a segregated phase of dispersed CuO particles between cryptomelane nanorods.

(2) These particles present good contact with Mn-phase of the support at surface, leading to a positive Cu – Mn synergistic effect, whereas there is no interaction with K intratunnel species from cryptomelane.

(3) The presence of medium-sized CuO particles dispersed in cryptomelane in Cu/CR catalyst turns into the best performance for 7% Cu/CR in CO-PROX reaction, when compared to smaller and larger CuO particles, as in 4% Cu/CR and 11% Cu/CR, respectively.

(4) The most enhanced reducibility of 7% Cu/CR correlates well with its best CO-PROX catalytic activity, and the largest change in WF by the effect of Cu loading into cryptomelane, too. Both are signs of the strongest Cu – Mn interaction, which are indirect evidences of the maximization of Cu(I) states in the contact points to MnO<sub>x</sub> phase from cryptomelane support.

(5) According to *in situ* Work Function measurements, Cu/CR catalyst maximizes both O<sub>2</sub> uptake and CO interaction with regards to pure CuO and CR catalysts, evidencing the active role of interfacial labile Cu – O – Mn entities.

(6) On the other hand, whereas CuO<sub>x</sub> phase enhances O<sub>2</sub> restitution capacity in Cu/CR catalyst, cryptomelane promotes surface Cu(I) states that increase CO interaction with the catalytic surface.

(7) The presence of medium-sized CuO particles exhibits a compromise between sufficient active Cu – Mn interface for the maximization of Cu(I) species, and stable CuO bulky sites for the efficient O<sub>2</sub> recovery upon MVK CO-PROX ongoing mechanism.

(8) Hence, for CuO/Cryptomelane, certain analogy with CuO/CeO<sub>2</sub> catalyst can be established since both supports are reducible oxides that promote interfacial Cu(I) active states by means of strong synergistic effect.

(9) The results presented herein evidence the large potential of cryptomelane as an active support for Cu-based catalysts towards CO-

PROX reaction application, although the stability of this material is not as good as in CuO/CeO<sub>2</sub> catalyst, but partially kept in CO<sub>2</sub> + H<sub>2</sub>O reaction conditions, in which CuO/Cryptomelane results particularly interesting.

Next Chapter 8 deals with a direct comparison between CuO/CeO<sub>2</sub> and CuO/Cryptomelane materials for catalytic CO-PROX application, in order to rationalize real opportunities of this alternative material, when compared to the well-established CuO/CeO<sub>2</sub> catalyst.

## CHAPTER 8

# Comparative analysis between CuO/CeO<sub>2</sub> and CuO/Cryptomelane: real opportunities in CO-PROX application

Chapter 8 compiles main remarks referring to CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalysts utilization in the Preferential CO Oxidation reaction and the most relevant outcomes achieved along the development of this Project Thesis are presented altogether for their direct comparison. With fresh sample on the reactor, CuO/Cryptomelane shows better performance than CuO/CeO<sub>2</sub> on a first catalytic run, but latter CuO/Cryptomelane deactivation on successive reaction cycles flips their relative activities. Nevertheless, in CO<sub>2</sub>+H<sub>2</sub>O environment, the enhanced stability of CuO/Cryptomelane allows to reach a much more active state after the succession of catalytic runs, which sets closer the CuO/CeO<sub>2</sub> and CuO/Cryptomelane performances, up to the point that the latter shows big competitive potential.

## 8.1 Introduction

During this Project Thesis, CuO/Cryptomelane and CuO/CeO<sub>2</sub> catalysts have been prepared, fully characterized and tested in the Preferential CO Oxidation (CO-PROX) reaction in presence of large H<sub>2</sub> excess. The results achieved from the research work presented so far clearly reveal the large potential of CuO/Cryptomelane catalyst and its promising real opportunities to leverage CeO<sub>2</sub>-based catalysts substitution for the sake of a more sustainable approach into the exhaustive catalytic CO clean-up required for H<sub>2</sub> purification. Nonetheless, stability issues attributed to partial collapse of cryptomelane structure evidenced, by the segregation into Mn<sub>3</sub>O<sub>4</sub> and CuMn<sub>2</sub>O<sub>4</sub> crystalline phases, forced by ongoing oxidation – reduction cycles, is a strong limiting barrier towards the widespread utilization of CuO/Cryptomelane, although regeneration treatments have demonstrated to partially prevent this deactivation [1].

In Chapter 6, though, it was checked that when CO-PROX reaction test is performed in CO<sub>2</sub>+H<sub>2</sub>O presence, CuO/Cryptomelane was less prone to deactivation on each catalytic run, and it was not even necessary to undertake any regeneration intermediate pre-treatment in between cycles [2]. Interestingly, the introduction of CO<sub>2</sub>+H<sub>2</sub>O, potential inhibitors in CO-PROX catalysts, lead to an improved stability over CuO/Cryptomelane, which was attributed to the partial relocation of intra-tunnel water species, with structural stabilizing effect, that hold back cryptomelane collapse into the inactive segregated phases. Furthermore, the co-presence of CO<sub>2</sub> leads to a magnified H<sub>2</sub>O and CO<sub>2</sub> retention capacity with regards to standalone H<sub>2</sub>O and CO<sub>2</sub> addition, which tentatively involves different mechanisms of adsorption/incorporation on the CuO/Cryptomelane surface. Namely, the effect of carbonate formation and its participation in H<sub>2</sub>O co-adsorption mechanism via bicarbonates, with higher affinity with the acid cryptomelane surface than carbonates. Yet, the blocking effect of CO<sub>2</sub> molecules, which impedes redox exchange in Cu – O – Mn entities leading to a reducibility loss, which is negative for the catalytic activity, but positive for the stability since it restrains the deactivating redox cycling and eventually maintains the intrinsic good H<sub>2</sub>O affinity of better-kept cryptomelane.

Conversely, CuO/CeO<sub>2</sub> catalysts are reported to be affected by CO<sub>2</sub>+H<sub>2</sub>O presence, although they exhibit absolute stability upon cyclability in successive CO-PROX catalytic runs, as well as good performance in long time-on-stream CO-PROX tests, as it was confirmed in Chapter 4 [3]. The enhanced stability is attributed to the large lattice adaptability upon changes in Ce<sup>3+</sup>/Ce<sup>4+</sup> ratios, allowing the easy oxygen vacancy formation that leads to excellent catalytic activity, but more importantly, the facile lattice oxygen re-accommodation with incoming O<sub>2</sub> molecules from the gas phase. The latter is a key feature, since enables entire reversibility in the reduction – oxidation processes over CeO<sub>2</sub> catalysts, in contrast the inefficient oxygen restitution from Cryptomelane catalysts.

At this stage, having presented all along this Thesis parallel studies on CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalyst by separate, Chapter 8 aims to compile main relevant outcomes from the separate studies, while providing at the same time, further coordinate characterization results for the sake of their direct benchmarking.

## 8.2 Experimental Section

The synthesis of CuO/Cryptomelane and CuO/CeO<sub>2</sub> catalysts (5% wt. Cu) was conducted according to procedure detailed in [Section 2.1.1](#) from Chapter 2, which is repeatedly followed all along the Project Thesis.

Both prepared materials were tested in CO-PROX catalytic tests according to the experimental settings and specific conditions as stated in [Section 2.2.3](#), which include stability tests upon cyclability in the set of conditions: CO+H<sub>2</sub>+O<sub>2</sub>; CO+H<sub>2</sub>+O<sub>2</sub>+CO<sub>2</sub>; CO+H<sub>2</sub>+O<sub>2</sub>+H<sub>2</sub>O; and CO+H<sub>2</sub>+O<sub>2</sub>+CO<sub>2</sub>+H<sub>2</sub>O, conducted by means of the introduction, either separated or together, of 9% CO<sub>2</sub> and 5% H<sub>2</sub>O in the reactant gas mixture feeding.

CuO/Cryptomelane and CuO/CeO<sub>2</sub> catalysts were characterized in fresh and spent samples by means of several techniques as presented in Chapter 2. Namely, N<sub>2</sub> adsorption at -196°C for the assessment of textural properties ([Section 2.2.2.1](#)); X-Ray Diffraction (XRD) for the crystalline characterization ([Section 2.2.2.2](#)); Temperature Programmed Reduction with H<sub>2</sub> (H<sub>2</sub>-TPR), as explained in [Section 2.2.2.4](#); and Temperature Programmed Desorption (TPD) experiments, CO<sub>2</sub>-, H<sub>2</sub>O-, and CO<sub>2</sub>+H<sub>2</sub>O-TPD, as detailed in [Section 2.2.2.5](#).

Finally, results from isotopic <sup>36</sup>O<sub>2</sub> pulse experiments conducted over CuO/CeO<sub>2</sub> and CuO/Cryptomelane are herein presented and discussed. Instrumental details and specifications regarding these experiments were exposed in [Section 2.2.4.3](#).

## 8.3 Results

### 8.3.1 CO-PROX activity tests

#### 8.3.1.1 Effect of CO<sub>2</sub>, H<sub>2</sub>O and CO<sub>2</sub>+H<sub>2</sub>O

Figure 8.1 gathers the CO-PROX activity results in a first run in different set of experimental conditions for CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalysts in Figures 8.1a,b) and 8.1c,d) respectively. Accordingly, the inhibiting effect of CO<sub>2</sub>, H<sub>2</sub>O and CO<sub>2</sub>+H<sub>2</sub>O mixture in the reactor feeding stream into each catalyst is observed.

**Figure 8.1.** CO-PROX activity results in terms of (a,c) CO conversion (%); and (b,d) CO selectivity (%) with (a,b) CuO/CeO<sub>2</sub>; and (c,d) CuO/Cryptomelane catalysts.

As thoroughly discussed along Chapter 6, the CO-PROX catalytic activity of CuO/Cryptomelane is not much affected by CO<sub>2</sub> presence, but is highly sensitive to H<sub>2</sub>O, and the combined CO<sub>2</sub>+H<sub>2</sub>O feeding is the most detrimental condition, as expected. The irregular S-shape of the CO conversion profiles is tentatively assigned to structural and redox redistributions in the CuO/Cryptomelane catalyst along the reaction course, while in CO<sub>2</sub>+H<sub>2</sub>O conditions this observation is not applicable provided the major stability of the catalyst. The CO selectivity profiles are affected by H<sub>2</sub>O presence, showing a sharper lowering after H<sub>2</sub> oxidation reaction *on-set* as inhibitor of H<sub>2</sub> oxidation reaction in H<sub>2</sub>O and CO<sub>2</sub>+H<sub>2</sub>O conditions.

On the contrary, for CuO/CeO<sub>2</sub> catalyst, the CO conversion profiles presented in Figure 1a show for the whole set of tested conditions identical well-defined sigmoidal shapes but moved along the temperature range according to their particular degree of inhibition, which correlates as follows: CO<sub>2</sub> < H<sub>2</sub>O < CO<sub>2</sub>+H<sub>2</sub>O. On the other hand, the presence of CO<sub>2</sub>, H<sub>2</sub>O and CO<sub>2</sub>+H<sub>2</sub>O mixture in the feeding shifts equally the CO selectivity profiles shown in Figure 1b which appear overlapped in these three conditions. That is to say, the CO/H<sub>2</sub> competition is kept constant with independence of whether CO<sub>2</sub> or H<sub>2</sub>O is present, which is an interesting remark that leads to the conclusion that the main inhibition mechanism is due to surface blocking rather than thermodynamic aspects of the oxidation reactions by equilibria shifting, in contrast with CuO/Cryptomelane catalyst.

Thus, in agreement to the discussion presented in Chapter 4, CO<sub>2</sub> forms in a large extent stable carbonate, formate and bicarbonate species in

the CuO/CeO<sub>2</sub> catalyst surface that would hinder interfacial Cu – Ce interaction and eventually block active sites for both CO and H<sub>2</sub> oxidation. In the first case, because of the decrease in the abundance of partially reduced Cu<sup>+</sup> species (CO oxidation active sites) as a result of the hampered Cu – Ce interaction; and in the second case, because the stabilization of carbonaceous surface groups would prevent catalyst reduction up to Cu<sup>0</sup> state (H<sub>2</sub> oxidation site).

On the other hand, it is expected that H<sub>2</sub>O may be massively physisorbed as molecular water, besides forming surface hydroxyls that would partially reduce the CeO<sub>2</sub> surface. According to the discussion presented in Chapter 4, the presence of surface hydroxyls turns in positive for CO oxidation activity at low temperatures by the preferential formation of hydrogen-based carbonaceous species with lower thermal stability and faster active site release. However, the presence of ample OH-covered surfaces is detrimental, apart from the surface blocking and reactants limited access, by the large reduction extension of the CeO<sub>2</sub> surface, which shifts the redox Cu<sup>2+</sup>/Cu<sup>+</sup> - Ce<sup>3+</sup>/Ce<sup>4+</sup> interplay stabilizing Cu<sup>2+</sup> with regard to Cu<sup>+</sup>. Hence, despite the presence of surface Ce(III) cations is generally attributed to be positive since the concomitant formation of O vacancy defects, which induce a higher oxygen mobility and eventually more active oxygen, the Ce(IV) reduction by OH formation does not bring such positive consequence as the extra electron is well-located in the Ce<sup>3+</sup> –O– H ends.

Additionally, comparing the results of CO<sub>2</sub> and H<sub>2</sub>O addition into CO-PROX conversion profiles, H<sub>2</sub>O causes more damage to CO conversion than CO<sub>2</sub>, which proves the very large affinity of the basic CeO<sub>2</sub> surface to get hydroxylated and covered by water molecules. Finally, the combined CO<sub>2</sub>+H<sub>2</sub>O addition to the reactor leads to the worst performance, being additive the detrimental effects of their individual action, probably, as in the case of CuO/Cryptomelane, because of the major surface coverage provided by the enhanced CO<sub>2</sub>/H<sub>2</sub>O co-adsorption [2].

#### 8.3.1.2 Catalysts stability in CO-PROX reaction conditions

The stability and cyclability of CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalysts was evaluated conducting several reaction runs in the different CO-PROX ambient conditions. Figures 8.2a and 8.2b show the temperature for the 50% of CO conversion (T<sub>50</sub>) along 4 catalytic runs without pre-treatment in between.

**Figure 8.2.** Temperature for the 50% of CO conversion ( $T_{50}$ ) in 1-4 cycles of CO-PROX reaction in different environment mixtures with (a) CuO/CeO<sub>2</sub>; and (b) CuO/Cryptomelane catalysts.

Comparing in qualitative view Figures 8.2a and 8.2b, CuO/CeO<sub>2</sub> presents a stable behavior along 4 cycles of reaction for each and every condition tested, whereas CuO/Cryptomelane suffers from a deactivating process of different magnitude depending on the reaction environment, as thoroughly detailed in Chapter 5. In particular, at the first run CuO/Cryptomelane presents an enhanced catalytic activity with regards to CuO/CeO<sub>2</sub>, which is evidenced by a lower  $T_{50}$  for all the set of conditions. However, the severe deactivation of CuO/Cryptomelane and the excellent stability of CuO/CeO<sub>2</sub> lead to the opposite trend after the second cycle of reaction. Thus, when CuO/Cryptomelane reaches a stationary performance on its cyclability, CuO/CeO<sub>2</sub> presents a better performance. Nevertheless, as it was concluded in Chapter 7, the catalytic performance of CuO/Cryptomelane in the, apparently, most detrimental conditions (CO<sub>2</sub>+H<sub>2</sub>O), representative of real CO-PROX reaction operation, allows to achieve relevant CO conversion and CO selectivities in the convenient

temperature ranges of this application, overcoming the catalytic performance than when free of both or either CO<sub>2</sub> or H<sub>2</sub>O.

This particular feature of CuO/Cryptomelane, attributed to an enhanced stability of Cryptomelane material with CO<sub>2</sub>+H<sub>2</sub>O presence in CO-PROX reaction environment, leads to a comparable performance to CuO/CeO<sub>2</sub> in the same reaction settings, which are the most detrimental. As a result, CuO/Cryptomelane catalyst is a potential competitor to CuO/CeO<sub>2</sub> when real CO-PROX operation conditions are tested, including CO<sub>2</sub> and H<sub>2</sub>O in the reactor feeding stream, although CuO/CeO<sub>2</sub> still presents an improved performance.

This conclusion leads to important consequences since Cryptomelane material is inexpensive, natural and abundant, and therefore is not involved in any environmentally-damaging extraction process as it occurs with cerium-based materials under the umbrella of geopolitical RE metal interests. Therefore, new opportunities for Cryptomelane-based catalyst may arise given its multiple advantages and its excellent performance in real conditions of CO-PROX operation.

In order to shed some more light in the inhibition mechanism and CO<sub>2</sub>/H<sub>2</sub>O relative affinities of both CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalysts, temperature programmed desorption experiments are presented in next Section.

### **8.3.2 Temperature Programmed Desorption (TPD) experiments**

Figure 8.3 shows the TPD profiles for CuO/CeO<sub>2</sub> and CuO/Cryptomelane after different conditioning pre-treatments, namely: CO<sub>2</sub> saturation (CO<sub>2</sub>-TPD), H<sub>2</sub>O saturation (H<sub>2</sub>O-TPD) and CO<sub>2</sub>+H<sub>2</sub>O saturation (CO<sub>2</sub>+H<sub>2</sub>O-TPD). Results corresponding to CuO/Cryptomelane were previously presented in Figures 6.3 from Chapter 6.

**Figure 8.3.** Monitored MS signals (a,b) 44, CO<sub>2</sub>; (c,d) 18, H<sub>2</sub>O; and (e,f) 32, O<sub>2</sub> for (a,c,e) CuO/CeO<sub>2</sub>; and (b,d,f) CuO/Cryptomelane catalysts in CO<sub>2</sub>-TPD; H<sub>2</sub>O-TPD and (CO<sub>2</sub> + H<sub>2</sub>O)-TPD experiments.

Comparing CuO/CeO<sub>2</sub> with CuO/Cryptomelane, it is evidenced in Figures 8.3a-f how CuO/CeO<sub>2</sub> is thermally more stable, since the control experiment (with no saturation pre-treatment) presents a flat product release. Moreover, no O<sub>2</sub> is released in the heating up to 650°C (Figure 3e), in contrast with CuO/Cryptomelane (Figure 8.3f) which starts decomposing above 450°C to Mn<sub>2</sub>O<sub>3</sub> [5].

Firstly, CO<sub>2</sub> saturation pre-treatment turns into a larger CO<sub>2</sub> release, which is compatible with the more basic nature of CeO<sub>2</sub> support and its great capacity to stabilize carbonaceous species on surface. On the other hand, H<sub>2</sub>O product is also observed after this treatment, in a non-coupled release with regards to CO<sub>2</sub>, which could be explained by the forced hydroxyl decomposition upon carbonate formation by CO<sub>2</sub> contact.

Nevertheless, in the opposite way this effect is maximized since H<sub>2</sub>O saturation pre-treatment leads to a larger CO<sub>2</sub> release than even after CO<sub>2</sub> treatment. Interestingly, this CO<sub>2</sub> desorption is retarded with regard to CO<sub>2</sub>-TPD profile, but coupled with H<sub>2</sub>O desorption, which could be tentatively ascribed as the decomposition of bicarbonate species formed when intrinsic

and stable carbonates in CeO<sub>2</sub> surface interact with incoming H<sub>2</sub>O molecules. Thus, H<sub>2</sub>O interaction in CuO/CeO<sub>2</sub> catalyst forces CO<sub>2</sub> release of stable carbonates, and such effect is even more clearly observed in the concomitant CO<sub>2</sub> + H<sub>2</sub>O saturation mixture, leading to the maximum product evolution in CO<sub>2</sub>/H<sub>2</sub>O coupled profiles, in analogy with CuO/Cryptomelane. Therefore, it may be a common feature for both the preferential formation of bicarbonate species or hydrogenated carbon intermediates as carboxylates, or formates when CO<sub>2</sub> and H<sub>2</sub>O co-adsorb in the catalytic surface. In the case of CuO/Cryptomelane, its low affinity towards CO<sub>2</sub> chemisorption leads a very impressive growth in CO<sub>2</sub> release, driving to the conclusion that bicarbonates can be stabilized into cryptomelane acidic surface, but not much carbonates, in contrast with CeO<sub>2</sub>.

As a result, TPD experiments prove that CuO/CeO<sub>2</sub> catalyst presents a great thermal stability and a higher sensitivity to CO<sub>2</sub> and H<sub>2</sub>O exposure, accommodating easily carbonates, adsorbed water and other intermediate products upon the saturation treatments. The larger product emission when compared to CuO/Cryptomelane, indicates that CuO/CeO<sub>2</sub> is more susceptible to surface blocking upon CO<sub>2</sub> and H<sub>2</sub>O pre-treatments, from which the latter shows most intense effect. This trend explains the catalytic activity observed in the first cycle in the different conditions tested for CuO/CeO<sub>2</sub>, where H<sub>2</sub>O leads to a larger inhibition than CO<sub>2</sub>, and it should be attributed to a higher surface blockage. In contrast, acid Cryptomelane surface has no affinity to retain CO<sub>2</sub>, for which the catalytic performance of CuO/Cryptomelane catalyst is not much affected by CO<sub>2</sub> presence, whereas H<sub>2</sub>O is deactivating in a large extent.

On the other hand, to study in detail the reason for the different evolution of the catalytic activity along cycles for CuO/CeO<sub>2</sub> and CuO/Cryptomelane in each of the experimental settings tested, physicochemical characterization of fresh and spent samples is presented in the following section. For the sake of brevity, only the used samples from the tests in CO+O<sub>2</sub>+H<sub>2</sub> and CO+O<sub>2</sub>+H<sub>2</sub>+CO<sub>2</sub>+H<sub>2</sub>O conditions were analyzed, besides the fresh samples.

### 8.3.3 Physicochemical characterization of fresh and spent samples

#### 8.3.3.1 X-Ray diffraction (XRD)

Figures 8.4a and 8.4b show XRD results from CuO/CeO<sub>2</sub> and CuO/Cryptomelane fresh and spent samples.

**Figure 8.4.** X-Ray diffractograms for **(a)** CuO/CeO<sub>2</sub> and **(b)** CuO/Cryptomelane fresh and used catalysts.

Figure 8.4a exhibits a clear stable maintenance of CuO/CeO<sub>2</sub> catalyst crystalline structure, displaying a typical X-Ray diffractogram of CeO<sub>2</sub> fluorite lattice. The presence of CuO tenorite phase is not detected in any case, for which significative CuO sintering is tentatively ruled out. On the other hand, as Table 8.1 displays, there are no important differences in the crystallite size calculated by means of Debye-Scherrer equation [6–8] and Williamson-Hall (WH) [9,10], and the calculated lattice parameter correlates well with the characteristic CeO<sub>2</sub> cell unit. In conclusion, CuO/CeO<sub>2</sub> is stable and presents identical crystalline features before and after reaction.

**Table 8.1.** Crystallographic features of CuO/CeO<sub>2</sub> samples fresh and used in different conditions. Scherrer calculations and lattice constant “a” are referred to (111) peak from cubic fluorite structure.

CuO/CeO <sub>2</sub> sample	Lattice constant (nm)	Crystal Scherrer (nm)	Crystal size WH (nm)
Fresh	0.5392	10	14
Used in CO+O <sub>2</sub> +H <sub>2</sub> conditions	0.5401	9	15
Used in CO+O <sub>2</sub> +H <sub>2</sub> +CO <sub>2</sub> +H <sub>2</sub> O conditions	0.5411	10	14

On the contrary, CuO/Cryptomelane displays a poor stability upon CO-PROX reaction course in CO + O<sub>2</sub> + H<sub>2</sub> conditions, where Mn<sub>3</sub>O<sub>4</sub> hausmannite phase is the main crystalline phase detected by XRD. As previously explained in detail in Chapter 6, cryptomelane structure is not stable upon reduction and oxidation cycles ongoing during CO-PROX reaction mechanism. However, the co-addition of CO<sub>2</sub> + H<sub>2</sub>O to the CO-PROX gas reactant mixture leads to an improved stability of cryptomelane phase, that also results in the best catalytic performance at the forth cycle.

The ratio between the intensities of (211) peaks from cryptomelane phase centred at 37.45° and (211) from hausmannite centred at 36.1°, allows to roughly measure the degree of transformation. Table 8.2 also shows the calculated crystallite size using Scherrer equation for the (211) peak and cell parameters (a) and (c) according to cryptomelane tetragonal unit cell for the fresh and used samples. Both parameters correlate well with reported values of cryptomelane structure (α-MnO<sub>6</sub>), being (a) 9.866 Å; and (c) 2.872 Å [11]. In the case of Mn<sub>3</sub>O<sub>4</sub> lone phase observed in CuO/Cryptomelane used sample in CO + O<sub>2</sub> + CO conditions, the cell parameter values fit as well with reported literature [12].

**Table 8.2.** Crystallographic features of CuO/Cryptomelane samples fresh and used in different conditions. % α-MnO<sub>2</sub> calculated by peak intensity ratios Scherrer calculations are referred to (211) peak from tetragonal phase.

CuO/Cryptomelane sample	% α-MnO <sub>2</sub>	Crystallite size Scherrer (nm)	“a” (nm)	“c” (nm)
Fresh	100	17	9.811	2.861
Used in CO+O <sub>2</sub> +H <sub>2</sub> conditions	0	11	-	-
Used in CO+O <sub>2</sub> +H <sub>2</sub> +CO <sub>2</sub> +H <sub>2</sub> O conditions	60	19	9.828	2.869

### 8.3.3.2 Temperature Programmed Reduction with $H_2$ ( $H_2$ -TPR)

The interaction strength and synergistic effect from CuO and the support in CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalyst can be determined by means of reducibility studies provided by  $H_2$ -TPR for the fresh and spent samples, as shown in Figures 8.5a and 8.5b.

**Figure 8.5.**  $H_2$ -TPR profiles for (a) CuO/CeO<sub>2</sub> and (b) CuO/Cryptomelane fresh and used catalysts.

Regarding Figure 8.5a, the reduction profiles for CuO/CeO<sub>2</sub> catalyst are presented only for the low temperature region, where CuO and the promoted surface Ce<sup>4+</sup> reduction take place in two separate peaks that may be assigned to (1) finely dispersed CuO particles and (2) bulky CuO particles in concomitant reduction with interfacial Ce<sup>4+</sup> ions [13]. The profiles of the used CuO/CeO<sub>2</sub> samples show slight differences, which evidences changes in Cu – Ce interaction after the CO-PROX reaction cycles, by shifting the low temperature peak towards higher temperatures. The shifting is much more obvious in the sample used in CO<sub>2</sub> + H<sub>2</sub>O conditions, where the low temperature peak is overlapped under the evolved high temperature peak. These results provide hints of certain CuO sintering or Cu – Ce contact modification upon reaction course. Nevertheless, partial reduction of the fine CuO nanoparticles cannot be ruled out.

On the other hand, the reduction profiles for CuO/Cryptomelane samples exhibit large differences depending on the catalyst state, which were discussed in detail in Chapter 6. The characteristic  $H_2$ -reduction profile of CuO/Cryptomelane catalyst with anticipated reduction of CuO particles and MnO<sub>2</sub> reduction in two steps towards MnO has been previously described and well-reported [1]. Thus, whereas the spent sample in CO<sub>2</sub> + H<sub>2</sub>O conditions shows discrepancies with fresh sample, such as the

disappearing CuO reduction event, the manganese reduction events roughly keep the shape and position along temperature profile. However, for the sample used in the experiments free of CO<sub>2</sub> + H<sub>2</sub>O, the reduction profile presents a very different aspect, which can be attributed to the cryptomelane phase distortion and reduction towards hausmannite phase, in agreement with XRD results. Therefore, important crystalline and structural changes occur in the CuO/Cryptomelane catalyst undergoing CO-PROX reaction, and CO<sub>2</sub> + H<sub>2</sub>O conditions prevent from such deactivating processes.

In conclusion, the physicochemical characterization of fresh and used catalysts confirms the great stability of CuO/CeO<sub>2</sub>, while provides insights into the CuO/Cryptomelane deactivation mechanism. On the contrary, CuO/CeO<sub>2</sub> catalyst is active, selective and perfectly stable despite the slight differences observed, which do not reflect into activity loss after CO-PROX cyclability tests. The real opportunities for CuO/Cryptomelane catalyst in real CO-PROX operation would depend on the overcome of several challenges in terms of the maintenance of cryptomelane integrity, as proven in Chapter 5, a reoxidation treatment at high temperatures is a solution that partially hinders this deactivation process, as well as the presence of CO<sub>2</sub> + H<sub>2</sub>O in the reactor environment [2].

Finally, in order to complete this critical review analysis for the comparison of CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalyst, the mechanism of CO-PROX reaction is studied using <sup>36</sup>O<sub>2</sub> isotopic pulse experiments, results presented and discussed in the following section.

### 8.3.3 Isotopic <sup>36</sup>O<sub>2</sub> pulse experiments

Pulse oxygen isotopic experiments in CO-PROX conditions: 1% CO, 50% H<sub>2</sub> in 20 ml/min balanced He flow over 80 mg of catalyst were conducted at critical temperatures for both CuO/CeO<sub>2</sub> and CuO/Cryptomelane samples and the results are presented in Figure 8.6 and Figure 8.7, respectively. Regarding Figure 8.6, the results corresponding to the study over CuO/CeO<sub>2</sub> catalyst have been previously shown in Chapter 3, but for comparatively reasons are presented again in this section.

As discussed in Chapter 3, CuO/CeO<sub>2</sub> catalyst displays a behaviour typical for Mars-van Krevelen (MVK) mechanism, involving non-isotopic lattice oxygen in the CO oxidation and H<sub>2</sub> oxidation mechanisms at the three studied temperatures. The distribution of products CO<sub>2</sub> to H<sub>2</sub>O ratios correlates well with the selectivity profiles observed during fixed-bed catalytic tests, being fully selective to CO oxidation at 75°C, and the following decay with regards to H<sub>2</sub> oxidation at the rising temperature. On the other hand, the effect of the temperature towards the exchange capacity is not much relevant, given the narrow range of temperatures tested, resulting in a constant but high exchange capacity and the formation of mainly non-isotopic products. As commented previously in Chapter 3, whereas <sup>20</sup>H<sub>2</sub>O is not detected, the release of <sup>18</sup>H<sub>2</sub>O is observed in delay with regards to CO<sub>2</sub>

products, which is attributed to major desorption limitations of  $\text{H}_2\text{O}$  from the surface of  $\text{CeO}_2$ .

**Figure 8.6.** MS monitored signals after  $^{36}\text{O}_2$  pulses in CO-PROX conditions with  $\text{CuO/CeO}_2$  catalyst at 75, 100 and 150°C.

Worth to mention that for all the tested temperatures,  $\text{O}_2$  signals were not detected after the pulses, which indicates that the oxygen-poor environment of the experiments in the highly reducing  $\text{CO}+\text{H}_2$  atmosphere

leads to a great population of anionic vacancies creation into the CuO/CeO<sub>2</sub> catalyst. In this state, the catalyst absorbs the pulse of <sup>36</sup>O<sub>2</sub>, accommodating oxygen into the lattice and recovering partially the network, which eventually destabilises the adsorbed CO and H<sub>2</sub> molecules, and produces their oxidation in the adsorption sites with non-isotopic lattice oxygens.

**Figure 8.7.** MS monitored signals after <sup>36</sup>O<sub>2</sub> pulses in CO-PROX conditions with CuO/Cryptomelane catalyst at 75, 100 and 150°C.

On the contrary, Figure 8.7 shows analogue results obtained for the CuO/Cryptomelane isotopic pulse experiments, and significative differences with regards to CuO/CeO<sub>2</sub> are observed. In order to accurately interpret and discern CuO/CeO<sub>2</sub> and CuO/Cryptomelane behaviour, the MS signals were integrated and normalized in terms of total O species (CO<sub>2</sub> + H<sub>2</sub>O + O<sub>2</sub>) after the pulse.

Figures 8.8a and 8.8b present for CuO/CeO<sub>2</sub> and CuO/Cryptomelane, respectively, the integrated signals for the released products from H<sub>2</sub>O and CO<sub>2</sub> formation upon H<sub>2</sub> and CO oxidation after the pulse (solid symbols), as well as the overall outlet H<sub>2</sub>O, CO<sub>2</sub> and O<sub>2</sub> measured (open symbols). Hence, CO<sub>2</sub> and H<sub>2</sub>O product distribution ratio is more complex for CuO/Cryptomelane and relevant differences arise according to the pulse temperature.

**Figure 8.8.** MS integrated signals after <sup>36</sup>O<sub>2</sub> pulse in CO-PROX conditions with CuO/CeO<sub>2</sub> catalyst at 75, 100 and 150°C. **Open symbols:** normalized overall released products (ΣX): CO<sub>2</sub> (**diamonds**); H<sub>2</sub>O (**squares**); and O<sub>2</sub> (**circles**). **Solid symbols:** isotopic distribution among CO<sub>2</sub> (**diamonds**) and H<sub>2</sub>O (**squares**) species. **(a)** CuO/CeO<sub>2</sub>; **(b)** CuO/Cryptomelane.

The release of a large amount of H<sub>2</sub>O at low temperatures disrupts the well-correlated CO selectivity profiles of pulse experiments to fix-bed catalytic tests as in CuO/CeO<sub>2</sub> catalyst. Furthermore, the distribution of CO<sub>2</sub> and H<sub>2</sub>O products is a mixture between isotopic and non-isotopic, rather than clearly non-isotopic as for CuO/CeO<sub>2</sub>, which demonstrates the poorer oxygen exchange capacity of CuO/Cryptomelane.

In agreement with such statement, in contrast with CuO/CeO<sub>2</sub>, CuO/Cryptomelane releases O<sub>2</sub> species after the pulse, which evidences its lower re-oxidation capacity and, thus, lower oxygen mobility. In this regard, Figure 8.9 displays the amount of O<sub>2</sub>-type species after the pulse for CuO/Cryptomelane catalyst, and it shows that it is only at 150°C when all the pulsed O<sub>2</sub> is absorbed by the catalyst into the recovery of lattice oxygen.

**Figure 8.9.** MS monitored normalized signals after <sup>36</sup>O<sub>2</sub> pulses in CO-PROX conditions with CuO/Cryptomelane catalyst at 75, 100 and 150°C. **(Solid symbols):** overall O<sub>2</sub> released species in the outlet flow; **(open symbols):** isotopic distribution among H<sub>2</sub>O and CO<sub>2</sub> species.

Meanwhile, from 75 to 100°C, the release of O<sub>2</sub> species is lowered and the isotopic contribution grows, suggesting major O<sub>2</sub> absorption that does not result in an apparent exchange capacity improvement with the low temperature increase. Compared to CuO/CeO<sub>2</sub>, which does not present evolved O<sub>2</sub> signals after the pulses, CuO/Cryptomelane has much less active O<sub>2</sub> mobility, being unable to accommodate the integrity of the incoming O<sub>2</sub> molecules in its oxygen-deficient crystalline network by the highly reducing conditions of the experiment. Additionally, most of the O<sub>2</sub> released is of isotopic nature, originally coming from the <sup>36</sup>O<sub>2</sub> pulse, confirming the lower oxygen exchange capacity of CuO/Cryptomelane.

Therefore, most of incoming isotopic <sup>36</sup>O<sub>2</sub> molecules react with the highly abundant surface hydroxyl groups present by the effect of H<sub>2</sub>-rich environment, producing isotopic <sup>20</sup>H<sub>2</sub>O that is quickly released and detected

in the MS in very important proportion. On the other hand, the  $O_2$  pulse destabilizes HO and  $H_2O$  molecules formed upon O lattice interaction, resulting in a significant non-isotopic  $^{18}H_2O$  co-emission. Interestingly, two contributions of  $^{18}H_2O$  release can be discerned, being the first anticipated and concomitant with  $^{20}H_2O$  and  $CO_2$  release, and the second, delayed, in analogue manner, to  $H_2O$  released when CuO/CeO<sub>2</sub> catalyst pulse experiments. These results must be compared to  $H_2O$ -TPD profiles (Figure 8.3d), where CuO/Cryptomelane would exhibit two types of  $H_2O$  release in the low temperature region, attributed to surface-related water and water bounded inside the 2 x 2 tunnels.

In this case, since the release of surface  $H_2O$  is retarded because of its limited desorption rate when compared to  $CO_2$ , as it occurs in CuO/CeO<sub>2</sub> catalyst, the first  $H_2O$  contribution must be tentatively assigned to intratunnel water molecules, that quickly partially exchange part of O with incoming  $^{36}O_2$  molecules, resulting in a sharp co-emission of  $^{18}H_2O$  and  $^{20}H_2O$  coupled to  $O_2$  pulse. As it was studied previously, the great activity of CuO/Cryptomelane catalyst is related to the presence of highly mobile water species hosted in the tunnels, which provide good ionic mobility and stabilize the cryptomelane framework. Thus, it is unfair to conclude preliminary that CuO/Cryptomelane has a much poorer oxygen exchange capacity, since its crystalline nature and activity depend on such intratunnel-bounded  $H_2O$  molecules, as partial O exchange in water is indeed observed.

As a final remark, the lowering of anticipated  $H_2O$  release with the rising of temperature is in agreement with XRD and TPR characterization, which suggest cryptomelane collapse towards the formation of the average reduced  $Mn_3O_4$  spinel phase, probably by the massive water loss in the redox cycles suffered in CO-PROX reaction conditions. So that, when temperature is higher in the reducing CO-PROX conditions of the pulse experiments, the CuO/Cryptomelane catalyst is more reduced and consequently, the amount of released water decreases, until at 150°C, cryptomelane is in overall reduced. In such state, such intra-tunnel water species are not found or the remaining keep so tightly bounded that are not mobilized after the pulse.

It is only at 150°C when outlet water comes only from  $H_2$  oxidation reaction, and, in comparison with CuO/CeO<sub>2</sub>, the release of such delayed  $H_2O$  release has a clear more important contribution in the overall  $CO_2 + H_2O$  distribution products, as shown in Figure 8b. This apparent lower CO selectivity of CuO/Cryptomelane has to be critically rationalized, given the large affinity of CuO/Cryptomelane for water and the strong driving force for its favored release in the highly reducing conditions of the experiment.

Nevertheless, the isotopic  $CO_2$  components are free of this masking effect from cryptomelane intrinsic water, and compared to CuO/CeO<sub>2</sub>, CuO/Cryptomelane exhibits less contribution for the non-isotopic  $^{44}CO_2$  species, that is, lower participation in the Mars van Krevelen mechanism, and accordingly, less active lattice oxygen species.

As a result, whereas CuO/CeO<sub>2</sub> promotes catalyst reoxidation with the incoming O<sub>2</sub> pulse molecules, being efficiently absorbed in the anionic lattice vacancies, CuO/Cryptomelane exchanges in first instance, O from intratunnel labile water molecules, and is unable to accommodate the integrity of O<sub>2</sub> pulse provided its lower ionic mobility. Thus, at 75 and 100°C, the O uptake from the pulse is high, but not 100%, since the preferred interaction with intratunnel water molecules with regards to O lattice restoration in the MnO<sub>6</sub> octahedra framework. In this scenario, only once the catalyst is fully reduced, cryptomelane accommodates or consumes the whole O<sub>2</sub> species from the pulse, but the temperature is high enough so that in this condition, the non-selective regime still leads to a very large H<sub>2</sub>O emission with regards to CO<sub>2</sub>, and therefore, H<sub>2</sub>O products are always majority in CuO/Cryptomelane, in contrast with CuO/CeO<sub>2</sub>.

These results provide interesting conclusions and evidence the very important role of the intratunnel water species in the catalytic activity of CuO/Cryptomelane material. These are, not only the reoxidation key sites, but also the oxygen labile species in cryptomelane framework and the stabilizing anchors beside K intratunnel species. Therefore, when H<sub>2</sub>O is supplied (or co-supplied next to CO<sub>2</sub>) in the reactor feeding for the CO-PROX catalytic tests, CuO/Cryptomelane keeps better performance along catalytic cycles, given its faster reoxidation capacity by the H<sub>2</sub>O restitution. Nevertheless, a positive complementary effect of CO<sub>2</sub> cannot be ruled out since the best performance at the forth cycle occurs in CO<sub>2</sub> + H<sub>2</sub>O conditions, as shown in Figure 8.2b. A possible explanation is the promotion of the H<sub>2</sub>O retention capacity and the maximization of H<sub>2</sub>O interaction with cryptomelane surface when H<sub>2</sub>O and CO<sub>2</sub> are co-supplied, as TPD results in Figure 8.3b show. According to this, CO<sub>2</sub>+H<sub>2</sub>O saturation leads to the preferential formation of low temperature desorbed water (150-300°C) in detrimental to the higher temperature desorbed water contribution (300-375°C), previously attributed to surface water and intratunnel water, respectively. In a critical overview, it may be inferred that CO<sub>2</sub> presence aids to stabilize intratunnel water, preventing its release after CO<sub>2</sub> + H<sub>2</sub>O contact with regards to lone H<sub>2</sub>O, and thus, cryptomelane structure stability is improved. The characteristic redox features is better maintained with the co-addition of CO<sub>2</sub>, as well as CO<sub>2</sub> retention is enlarged in the stabilization of hydrogen-carbonated intermediates. This substantial coating of labile carbonaceous intermediates with an ease desorption should protect O-lattice abstraction and cryptomelane reduction upon CO and H<sub>2</sub> oxidation reactions, resulting in a hindered activity, but eventually a greater stability.

## 8.4 Conclusions

The catalytic performance and CO-PROX occurring mechanism in CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalysts have been compared in the present Chapter, as a convergent study of the particular insights obtained in

the separate studies presented along previous chapters in this Project Thesis. The overview of this direct comparison allows to establish important conclusions regarding the critical use for CO-PROX operation of both promising materials, which are herein collected in the following lines:

(1) In a first cycle of CO-PROX reaction, the catalytic activity of CuO/CeO<sub>2</sub> and CuO/Cryptomelane catalysts is comparable, being both excellent materials for this application even in real operation conditions, including CO<sub>2</sub> + H<sub>2</sub>O in the feeding stream.

(2) Initially, the individual effect of the additive inhibitors depends on the degree of the interaction with the catalytic surface both. Whereas in CuO/CeO<sub>2</sub> both CO<sub>2</sub> and H<sub>2</sub>O act inhibiting by surface blockage, where H<sub>2</sub>O has more impact in the catalytic inhibition; CuO/Cryptomelane is not significantly affected by CO<sub>2</sub> presence but strongly inhibited by H<sub>2</sub>O. In any case, the co-supply of CO<sub>2</sub> + H<sub>2</sub>O leads to the most detrimental activity.

(3) The most important differences between CuO/CeO<sub>2</sub> and CuO/Cryptomelane arise when successive catalytic runs without pretreatments in between are conducted. Meanwhile in CuO/CeO<sub>2</sub>, the activity is well maintained along 4 catalytic cycles in all tested conditions, CuO/Cryptomelane suffers from severe deactivation related to structural collapse and partial reduction from cryptomelane phase (MnO<sub>2</sub>) to hausmanite (Mn<sub>3</sub>O<sub>4</sub>), and the extent of such deactivation is dependent on the inlet gas mixture.

(4) CO<sub>2</sub> + H<sub>2</sub>O conditions prevent CuO/Cryptomelane decomposition and allow to obtain for this catalyst the best performance at the forth cycle when the CO-PROX inhibiting effect is maximum and CuO/CeO<sub>2</sub> exhibits its worst behavior.

(5) CuO/Cryptomelane is tentatively claimed to be a potential competitor to CuO/CeO<sub>2</sub> and possesses great positive qualities as a promising catalyst towards CO-PROX reaction in real operation conditions.

(6) According to <sup>36</sup>O<sub>2</sub> isotopic pulse experiments, a key element of cryptomelane good oxidation activity is the molecular water bounded in the tunnels, which turn into quick oxygen exchange sites and species, in contrast with CuO/CeO<sub>2</sub>, which presents excellent O<sub>2</sub> uptake features by means of intrinsic high oxygen mobility.

(7) The relative participation of lattice oxygen in the mechanism of reaction (Mars van Krevelen contribution) is much more important in CuO/CeO<sub>2</sub> catalyst, evidenced by the larger emission of non-isotopic products after the pulses, whereas in CuO/Cryptomelane, incoming O<sub>2</sub> molecules preferentially interact with the labile H<sub>2</sub>O species hosted in the tunnels.

(8) A relevant feature to be considered for the good catalytic activity maintenance of CuO/Cryptomelane is the presence of H<sub>2</sub>O, for the restoration of intratunnel stabilizing species, in spite of the contrary negative effect by the inhibition of surface coverage.

(9) Far from inhibiting the catalytic performance, CO<sub>2</sub> inlet enlarges the positive effect of H<sub>2</sub>O in CO<sub>2</sub> + H<sub>2</sub>O conditions, attributed to an improved H<sub>2</sub>O retention capacity by means of the formation of hydrogen carbonate species. These species firstly inhibit by surface blockage but hold a role in the enhanced retention of H<sub>2</sub>O intratunnel molecules that result very positive at preventing the catalyst deactivation.

(10) As a final conclusion, Chapter 8 has shed some light in the potential opportunities of CuO/Cryptomelane catalyst towards CO-PROX reaction in real operation conditions. Nevertheless, the excellent catalytic behavior of CuO/CeO<sub>2</sub> has not been reached by CuO/Cryptomelane even in the most convenient comparable conditions (CO<sub>2</sub> + H<sub>2</sub>O in the forth catalytic cycle), given the proficient intrinsic performance of CuO/CeO<sub>2</sub> catalyst.

For this reason, the large scalability studies of CO-PROX reaction with high space velocity tests using 3D-printed cordierite monoliths, presented in Chapter 10, CuO/CeO<sub>2</sub> has been selected as the active phase, in order to guarantee a good stability and the possibility to successfully focus on the effect of monolithic shape and the adequation of the mechanism of reaction.

## CHAPTER 9

# 3D-printing technology for the fabrication of improved asymmetrical honeycomb monolith catalyst

Chapter 9 presents the study on the scalability of powdered copper-based active phases in medium-sized monolithic catalysts with unconventional designs prepared by means of 3D-printing technology. An improved honeycomb-like monolith with asymmetrical channels, where the channels section decrease along the monolith, was fabricated using a template prepared by 3D printing. A reference honeycomb monolith was also prepared in the same way but with conventional straight channels. Cu/Ceria active phase was loaded on these supports, and SEM-EDX, Raman spectroscopy and XRD showed that the supported active phase is similar on both monoliths. The supported catalysts were tested for CO oxidation in excess oxygen and for preferential CO oxidation in H<sub>2</sub>-rich mixtures (CO-PROX), and the catalyst with the improved support achieved higher conversions in both reactions. The supported catalyst with asymmetrical channels has two benefits with regard to the counterpart catalyst with conventional symmetrical channels: improves the reaction rate with regard to the conventional one because fits better to the equation rate, and favors the turbulent regime of gases with regard to the laminar flow that prevails in symmetrical channels.

## 9.1 Introduction

Three dimensions (3D) printing is doing successful advances in topics like chemistry [1] or medicine [2-4], among others. Heterogeneous catalysts have been also successfully prepared by 3D printing in the last few years. For instance, Thakkar et al. printed zeolite monoliths [5], aminosilica monoliths [6] and metal–organic framework monoliths [7] for CO<sub>2</sub> removal, and Michorczyk et al. [8] used 3D-printed templates to prepare methane oxidation catalysts. Li et al. [9] prepared monoliths of MFI and FAU zeolites by 3D printing for catalytic cracking of n-hexane and Tubío et al. [10] printed Cu/Al<sub>2</sub>O<sub>3</sub> monoliths for liquid-phase catalytic applications.

All these examples demonstrate that preparation of monolith catalysts is feasible by 3D printing, but it would be desirable to go a step further and use this technology to prepare catalysts that cannot be easily prepared by conventional procedures.

Conventional ceramic honeycomb monoliths are prepared by extrusion of a proper paste, obtaining a bundle of symmetric and parallel channels. After thermal stabilization of the monolith, the catalyst active phase is loaded on the channels surface, and all these preparation steps are already well optimized for commercial applications [11-15].

Manufacture of honeycomb supports by extrusion only permits fabrication of monoliths with parallel channels, but not monoliths with more complex designs. 3D printing opens new options for fabrication of substrates with higher freedom in the design [16], and in this line, Li et. al. [17] have recently reported the preparation of monolith catalysts with different channel networks using 3D-printing. Monoliths with straight and parallel cylindrical channels were prepared, which can be also prepared by extrusion, but also monoliths with tetrahedron and tetrakaidecahedron periodic structures. A Ni active phase was loaded on all these monoliths, concluding that the best catalytic results for syngas methanation are obtained in this case with monoliths with straight and parallel cylinders.

**Figure 9.1.** Scheme of channels for the (a) symmetrical and (b) asymmetrical monoliths designed and fabricated in this study.

In this Chapter, an improved honeycomb-like monolith has been prepared using 3D printing. This improved support consists of a honeycomb-like structure with asymmetrical channels (see Figure 9.1). Conventional and improved monoliths were prepared using 3D printing and were coated with the same active phase (5 wt. % Cu/Ceria). The catalysts were characterized and tested in two chemical reactions with practical relevance: CO oxidation in excess oxygen, which is relevant for gas pollution control, and preferential oxidation of CO in the presence of H<sub>2</sub> (CO-PROX), which is a topic of ongoing research for H<sub>2</sub> purification in fuel cells.

## 9.2 Experimental Section

### 9.2.1. Catalysts preparation

Two monolithic supports have been prepared, and their main design parameters are shown in Figure 1. The designs have been done with Cubify Invent software. Both monoliths consist of cylinders (length of 30 mm; diameter 24 mm) and 14 parallel channels. Channels of the symmetrical monolith have 2x2 mm square section and channels of the asymmetrical monolith have square section of 3x3 mm and 1x1 mm at the reactants inlet and outlet sides respectively. Note that, with these sections, the total area of the channels of both monoliths is equal (240 mm<sup>2</sup> per channel).

Polymeric templates with the designs shown in Figure 1 have been printed with a Project 1200 (3DSYSTEMS) 3D printer using ultraviolet curable polymer (Visijet FTX green). Both templates were filled with commercial cordierite paste (COR-MIK-MP) kindly provided by VICAR S.A. After drying, first at room temperature and at 80°C overnight afterwards, the templates were removed by combustion in static air at 500°C for 2 hours, using a heating rate of 1°C/min. Cordierite was finally sintered in air at 1250 °C for 2 hours upon heating at 3°C/min.

The cordierite porosity was sealed with  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> (Alfa Aesar) by dip coating [18], in order to avoid migration of the catalyst active phases into the cordierite body and to ensure that active phases are located on the channels surface. Both cordierite monoliths were dipped twice (once each side drying the monoliths in between) in  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> water suspension (11 wt. %), and after drying, were calcined at 900°C for 2 hours. The weight increase after calcination was 0.4 %.

The catalyst active phase, consisting of CuO/CeO<sub>2</sub>, was loaded afterwards. Ceria powder was prepared by calcination of cerium nitrate (Alfa Aesar) at 500°C for 4 hours and a water suspension with 10 g/ml was prepared with this powder. Both monoliths were dipped twice into this suspension (once each side drying the monoliths in between), and after

drying, were calcined at 600°C for 2 hours. The ceria loading achieved after calcination was 2 wt. % in both monoliths.

Finally, CuO was loaded (5% wt. copper on ceria basis) by impregnating the monoliths with a copper nitrate water solution (0.4% wt.). The monoliths were dried rapidly just after impregnation in a muffle furnace pre-heated at 200°C, to improve copper dispersion, and were calcined afterwards at 400°C for 2 hours using a heating rate of 2°C/min.

### 9.2.2 Catalysts characterization

The prepared catalysts were characterized by means of SEM-EDS microanalysis for the elucidation of the thickness and dispersion of the catalytic layers coating the monolithic substrates along the channels. Further details can be found in [Section 2.2.2.8](#) from Chapter 2.

The crystalline nature of cordierite supports and the active CuO/CeO<sub>2</sub> phase were studied by means of XRD, as described in [Section 2.2.2.2](#). Complementary crystalline characterization was conducted via Raman spectroscopy, as detailed in [Section 2.2.2.3](#).

### 9.2.3 Catalytic tests

The effect of the monolith geometry in the catalytic conversion when reaction behaves under chemical rate control has been studied using CO oxidation in excess oxygen as model reaction [19-20], and when reaction behaves under external gas diffusion rate control has been studied using the CO-PROX as model reaction [21-22].

The catalytic experiments were carried out in a stainless-steel cylindrical reactor using the experimental set-up presented in [Section 2.2.3](#), using GC for product gas separation coupled to TCD. In experiments in oxygen excess, the gas mixtures fed to the reactor was 1% CO + 17% O<sub>2</sub>, whereas in CO-PROX experiments it was fixed 1% CO + 1% O<sub>2</sub> + 30% H<sub>2</sub>, both with He balance. Mass flow controllers were used to prepare the inlet gas mixtures, and total gas flows were ranged from 400 to 700 ml/min.

In a typical experiment, the reaction gas mixture was fed to the reactor at room temperature for 30 min, and then the temperature was raised at 2°C/min until 200°C. Then, the reaction gas mixture was replaced by 5% O<sub>2</sub> in He, keeping this flow while cooling. After 15 minutes at 200°C the furnace was switched off and the reactor was cooled down without control of the cooling rate. Following this protocol, several consecutive experiments were performed with total reproducibility of the catalytic results in the two catalytic reactions tested, confirming the stability of the catalyst active phase under both reaction conditions. This was expected for CuO/CeO<sub>2</sub> catalysts [23], and this is one of the reasons for the selection of this active phase.

## 9.3 Results and Discussion

### 9.2.3 Catalysts characterization

Figures 9.2 and 9.3 show representative SEM images of the monoliths with symmetrical and asymmetrical channels, respectively, and the chemical mapping obtained by EDS for Si, Al and Ce. In both SEM images, the catalyst coating is observed on the top of the images and a cordierite wall is shown at the bottom, as confirmed by EDS chemical mapping.

**Figure 9.2.** SEM-EDS characterization of the monolith catalyst with **(left)** symmetrical channels; **(right)** asymmetrical design.

Ce mapping confirms that the catalyst active phase forms a uniform layer on the cordierite surface and that the diffusion of catalyst active phase into the cordierite walls has been properly prevented. Si belongs to cordierite ( $2\text{MgO} \cdot 5\text{SiO}_2 \cdot 2\text{Al}_2\text{O}_3$ ), and Al belongs both to cordierite and to  $\alpha\text{-Al}_2\text{O}_3$  loaded before the catalyst active phase to seal the cordierite porosity. Al and Si occupy the same area in the images, confirming that the cordierite porosity was properly sealed.

In conclusion, differences in the catalyst active phase coating between the monoliths with symmetrical and asymmetrical channels were not observed by SEM-EDS.

The catalysts were also characterized by XRD, and the diffractograms are included in Figure 9.3. For this characterization, the monoliths were cut and the X-Ray spot was focused on the surface of the active phase layer.

**Figure 9.3.** XRD characterization of the catalysts.

The X-ray diffractograms of the coated monoliths show the characteristic peaks of the fluorite structure of ceria at  $28.5^\circ$ ,  $33.1^\circ$ ,  $47.6^\circ$ , and  $56.5^\circ$ , corresponding to the (111), (200), (220), and (311) planes, respectively (JCPDS-340394). Few peaks of cordierite are also shown in both diffractograms, and the CuO peaks that could appear at  $35.5^\circ$  and  $38.8^\circ$  are not observed, indicating that copper oxide is well dispersed on the ceria support forming small crystallites. Proper dispersion of copper oxide is usually obtained on ceria due to the strong interaction between both phases. The crystallite size of ceria was determined with the Scherrer equation, being 12 nm for both supported catalysts, and the lattice parameter is also equal in both samples (0.5401 nm). This lattice parameter value is similar to that reported in the JCPDS-340394 standard. This XRD characterization

suggests that there are not relevant differences in the crystalline phases supported on the monoliths with symmetrical and asymmetrical channels, as expected.

This conclusion was confirmed by Raman spectroscopy characterization. Raman spectra of the active phases, which are included in Figure 9.4, show a single band at  $465.5\text{ cm}^{-1}$  that is assigned to the  $F_{2g}$  mode of the fluorite structure of ceria. This peak is related to the vibration of the oxide anions around its equilibrium position in the octahedral sites of the cubic cell. The position of the  $F_{2g}$  peak is the same for both monoliths, and this confirms that the ceria lattice is equal.

**Figure 9.4.** Raman characterization of the catalytic active phases.

In conclusion, SEM-EDS, XRD and Raman spectroscopy characterization indicate that the active phases are equal in the monoliths with symmetrical and asymmetrical channels, and therefore, differences in the catalytic behavior can be attributed to differences in the shape of the channels.

### 9.3.2 CO oxidation in oxygen excess

Figure 9.5 shows CO oxidation rates as a function of temperature obtained with the symmetrical and asymmetrical monoliths in oxidation experiments performed with excess oxygen, where it is demonstrated the benefit of the asymmetrical design with regard to the conventional symmetrical one.

**Figure 9.5.** Reaction rate as a function of temperature for CO oxidation experiments performed with excess oxygen (1 % CO + 17 % O<sub>2</sub> in He) under different total gas flows (ml/min): ■ 400, ● 500, ▲ 600, ◆ 700. Rates were measured with CO conversions < 10%.

The improvement obtained with the asymmetrical monolith can be explained considering reaction kinetics. The kinetic equation to describe the CO oxidation rate under the experimental conditions of these experiments can be derived assuming that O<sub>2</sub> concentration remains constant during the reaction, since this reactant is feed in a large excess.

Therefore, CO oxidation to CO<sub>2</sub> can be considered generically like a chemical reaction where a gas A is converted to B:

the reaction rate is described by  $A \xrightarrow{k} B$  Eq. 9.1

Reaction rate =  $-dP_A/dt = k \cdot P_A$  Eq. 9.2

Where first order kinetic has been assumed for A,  $P_A$  is the partial pressure of A,  $k$  is the reaction rate constant and  $t$  is the reaction time.

Integration of equation 9.2 with the boundary conditions

$$P_A = P_{A,initial} \text{ for } t = 0 \quad P_A = P_{A,final} \text{ for } t = \tau$$

yields equation 9.3

$$P_{A,final} = P_{A,initial} \cdot e^{-k \cdot \tau} \quad \text{Eq. 9.3}$$

which allows calculating the partial pressure of A ( $P_{A,final}$ ) after a certain time under reaction conditions ( $\tau$ ) for a particular initial partial pressure of A ( $P_{A,initial}$ ). The reaction rate can be calculated as a function of reaction time by substituting equation 9.3 in equation 9.2.

$$\text{Reaction rate} = k \cdot P_{A,initial} \cdot e^{-k \cdot \tau} \quad \text{Eq. 9.4}$$

This calculation predicts that the reaction rate decreases with time under reaction conditions, because the rate depends on the concentration of reactant A, and this reactant is consumed during the course of the reaction.

Considering a heterogeneous catalysis reaction taking place on a fluid that flows through a conventional honeycomb monolith, the reaction rate will be fastest when the fluid enters into the monolith and it will decrease along the channels, because the reactants are progressively depleted. In this system, the reaction time is the residence time of A inside the monolith, and for a constant gas flow, is proportional to the monolith length. The relationship between residence time ( $\tau$ ) and the average distance that a reactant molecule covers inside the channel ( $d$ ) is described by equation 9.5

$$\text{Residence time } (\tau) = S \cdot d/F \quad \text{Eq. 9.5}$$

where  $S$  is the channel section area and  $F$  is the gas flow. Substituting equation 5 in equation 3 yields

$$P_{A,\text{final}} = P_{A,\text{initial}} \cdot e^{-k \cdot S \cdot d/F} \quad \text{Eq. 9.6}$$

Equation 9.6 predicts the decrease of the reactant A partial pressure along the monolith length as a function of the channels section, kinetic rate constant and gas flow. For conventional monoliths with symmetrical channels, section  $S$  remains constant along the channel. Nevertheless, for asymmetrical monoliths with different inlet and outlet sections,  $S$  changes along the channel.

As an example, equation 9.6 has been used to simulate the decrease of A partial pressure along channels of total length = 30 mm, comparing a conventional monolith with square section  $S$  with an asymmetrical monolith with channels of  $2.25 \cdot S$  and  $0.25 \cdot S$  inlet and outlet square sections, respectively. Note that these section areas are consistent with those in the monoliths prepared in this study using 3D printing, and with these section areas the total areas of the symmetrical and asymmetrical channels are equal. The A partial pressure profiles obtained with this simulation have been plotted on Figure 9.6 for the symmetrical and asymmetrical monoliths.

**Figure 9.6.** Qualitative simulation predicted by equation 6 of the reactant A partial pressure along channels of monolith reactors with symmetrical (conventional) and asymmetrical geometry. Settings for the simulation: symmetrical channels with square section  $S$ ; asymmetrical channels with  $2.25 \cdot S$  and  $0.25 \cdot S$  inlet and outlet square sections, respectively. Monoliths length = 30 mm.

This simulation predicts that the asymmetrical monolith is more efficient than the symmetrical one, in agreement with the experimental results plotted in Figure 9.6, and for the same monolith length, the reactant conversion achieved with the asymmetrical monolith is predicted to be higher. As mentioned, honeycomb monoliths with asymmetrical channels cannot be prepared by convention extrusion procedures, but it is possible to use 3D printing for this purpose.

### 9.3.3 CO oxidation in CO-PROX conditions

The channels geometry also affects the fluid dynamics into the monoliths, and CO-PROX experiments were performed to analyze this effect. Figure 9.7 shows the CO conversions in CO-PROX experiments, where it is observed that the asymmetrical monolith achieves higher CO conversion than the symmetrical counterpart. Differences between both monoliths are observed above 130 °C, once high CO conversions are achieved and external gas diffusion is expected to play a key role in the reaction rate.

**Figure 9.7.** CO conversion as a function of temperature in CO-PROX experiments. (1% CO + 1% O<sub>2</sub> + 30% H<sub>2</sub>; total gas flow: 700 ml/min).

This improvement of the asymmetrical monolith can be explained considering the fluid regime into the channels. A fluid flowing through the channels of a monolith can follow a laminar or turbulent regime, depending on the total fluid flow and geometry of the channels. Laminar flow occurs when viscous forces are dominant, and is characterized by smooth fluid motion, while inertial forces dominate the turbulent flow, which tend to produce chaotic movement of the molecules into the fluid. Radial diffusion of molecules is significantly improved under turbulent regime with regard to laminar flow, and this radial diffusion plays a role in the conversion whether a heterogeneous catalysis reaction behaves under diffusional control of the rate. The Reynolds number is a dimensionless parameter that predicts if the flow regime is laminar or turbulent depending on the space velocity, density and viscosity of a fluid and geometry of the pipe (channel in the case of a monolith) where the fluid flows through.

It has been proposed that the flow regime is laminar for Reynolds numbers below ~1800 and turbulent above ~ 4000 [27], with a transition regime in between where neither the viscous nor the inertial forces prevail. The Reynolds number for the symmetrical monolith and the CO-PROX mixture used in this study is lower than 100, indicating that the laminar flow clearly prevails. In the laminar regime, the reactant molecules flowing in the center of the channel have less chance to reach the catalyst active phase layer coating the channel surface than those flowing near the walls, and that is why gas diffusion limits the reaction rate for high conversions. At high conversion, the molecules near the walls have already reacted, and the last reactant molecules left are those in the channels center, which are affected by radial diffusion restrictions in the laminar regime.

Nevertheless, the asymmetrical channels break the laminar flow as the channel diameter becomes progressively narrow, and for this reason, the conversions achieved with the asymmetrical channels are higher than those obtained with the symmetrical ones, as observed in Fig. 9.7 for high conversions.

In summary, the theoretical calculations predict that an asymmetrical monolith improves both the reaction rate and the radial diffusion of the molecules in comparison with a symmetrical monolith, and the experimental results confirm these theoretical predictions.

## 9.4 Conclusions

3D printing has been used to prepare a honeycomb-like cordierite monolith with asymmetrical channels that improves the performance of conventional honeycomb catalyst supports. 3D-printing technology overcomes the limitations of conventional manufacture procedures based on extrusion and gives higher freedom in the design of monolith supports with complex shapes.

Channels section of the improved asymmetrical monolith are larger at the reactants entrance side than in the exit side, improving with regard to conventional monoliths both the reaction rate, when reaction behaves under kinetic rate control, and the radial diffusion of reactants, when reaction behaves under external gas diffusion rate control. As proof of concept, a Cu/Ceria active phase loaded on conventional and improved honeycomb monoliths has been used to accelerate CO oxidation in excess oxygen and preferential CO oxidation in H<sub>2</sub>-rich mixtures.

# CHAPTER 10

## General conclusions

Universitat d'Alacant  
Universidad de Alicante

In this PhD Thesis, the Preferential CO Oxidation in presence of  $H_2$  excess, so-called CO-PROX reaction has been studied with active copper-based materials from different chemical nature but analogue synergistic redox properties: namely  $CuO/CeO_2$  and  $CuO/Cryptomelane$ . The work related in this Project Thesis comprises the preparation, full characterization, activity testing and CO-PROX mechanistic approach over both formulations, in order to unravel the key catalytic features for the sake of a deep understanding of the process and the critical evaluation of their real opportunities.

All along this PhD Thesis, specific conclusions have been presented on each research part as distributed in the different Chapters. As an outline compendium, these main research outcomes and most relevant achievements can be drawn in the following general conclusions:

1. From mechanistic studies over  $CuO/CeO_2$  catalysts in CO-PROX reaction, it can be concluded that the CO oxidation rate accelerated by copper oxide-cerium oxide catalysts in CO-PROX conditions correlates to the formation of the  $Cu^+$ -CO carbonyl above a critical temperature, being copper carbonyl formation the rate limiting step. However, desorption of carbon products formed in the ceria surface is the slowest step below this threshold temperature. The hydroxyl groups on the catalyst surface play a key role in determining the nature of the carbon-based intermediates formed upon CO chemisorption and oxidation, whose abundance depends on the redox features of the  $CuO/CeO_2$ -based catalysts. Essentially, hydroxyls favor the formation of bicarbonates with respect to carbonates, and catalysts forming more bicarbonates reach faster CO oxidation rates than those which favor carbonates. All tested  $CuO/CeO_2$ -based catalysts exhibited good catalytic activity in CO-PROX reaction, although the presence of dopants (20% at.) on the ceria lattice produced in general detrimental effect on the optimum performance of pure  $CuO/CeO_2$ .

2. The fundamental study presented herein on  $CuO/CeO_2$  catalyst with the use of cutting-edge experimental techniques and DFT modelling has disentangled the participation of  $CeO_2$  support in lattice oxygen restitution during CO-PROX reaction progress. Namely,  $O_2$  restoration takes place in  $CuO$  species when these are mostly oxidized, in the low temperature range. Then, CO-PROX reaction progress reduces  $Cu_xO$  particles in a gradual surface to “bulk” process by the lattice oxygen abstraction and  $CO_2$  release. The accelerated CO oxidation by the increasing temperature leads to a critical reduced state over  $Cu_xO$  particles that activate the undesired competitive  $H_2$  oxidation reaction, henceforward boosting at the same time,  $Cu_xO$  reduction to a much faster and larger extent. At such point of reducing state over  $Cu_xO$  particles, direct  $O_2$  uptake is not efficient and preferentially occurs on  $CeO_2$  support, which aids to O-restoration in the labile  $Cu - O - Ce$  redox joints. *Operando* CO-PROX NAP-XPS experiments revealed a

highly superficial reduction on  $\text{CeO}_2$  and the nature of event has been associated with lattice oxygen transfer to  $\text{Cu}_x\text{O}$  particles during O-restitution via  $\text{CeO}_2$ .

3. The active enrolment of  $\text{CeO}_2$  support in the catalyst reoxidation mechanism involves several implications that result in the improved performance of  $\text{CuO}/\text{CeO}_2$  with regards to any other  $\text{CuO}$ -supported catalyst, allowing absolute reversibility upon reduction – oxidation cycles in the ongoing CO-PROX reaction.

4. Cryptomelane mineral is an abundant, non-toxic material with a scalable easy and reproducible laboratory synthetic preparation that presents promising opportunities as an active catalyst for CO oxidation and CO-PROX reaction. The physico-chemical properties of Cryptomelane in terms of high oxygen mobility and facile redox cycling among the different Mn oxidation states remind of  $\text{CeO}_2$ , with a well-known oxygen storage capacity (OSC) upon the quick electronic exchange between  $\text{Ce}^{3+}/\text{Ce}^{4+}$  pairs, so it is postulated as a promising potential substitute of  $\text{CeO}_2$ -based catalytic systems.

5. In the same line, when Cryptomelane is loaded with copper oxide, conforming  $\text{CuO}/\text{Cryptomelane}$  formulations, the catalytic activity in CO-PROX reaction is largely improved because of the enhancement of its redox features relying on the formation of active  $\text{Cu} - \text{O} - \text{Mn}$  entities, that lead to the promotion of labile oxygen species with good interaction with reactant CO molecules.

6. The improved activity of  $\text{CuO}/\text{Cryptomelane}$  with regards to Cryptomelane, is though, counteracted by a major stability loss and significative deactivation after CO-PROX reaction catalytic cycles. The study over  $\text{CuO}/\text{Cryptomelane}$  deactivation mechanisms suggested that Cryptomelane's basic micro-structure consisting of well-defined tunnelled arrangements ( $\alpha\text{-MnO}_2$ ) partially collapses into the inactive phases  $\text{Mn}_3\text{O}_4$  and crystalline  $\text{CuMn}_2\text{O}_4$ , which involve an average reduction of manganese and copper species from initial  $\text{CuO}/\text{Cryptomelane}$  state. Thus, the redox promotion of Cu loading in  $\text{CuO}/\text{Cryptomelane}$  results positively in an activity gain for the MVK ongoing mechanism in CO-PROX reaction, but at the same time, its enhanced reducibility makes too easy lattice oxygen abstraction and  $\text{CuO}/\text{Cryptomelane}$  is eventually reduced and deactivated.

7. Potential regeneration strategies for  $\text{CuO}/\text{Cryptomelane}$  catalysts have been discussed, such as reoxidation pre-treatments in  $\text{O}_2$  atmospheres at different temperatures, namely  $200^\circ\text{C}$  and  $400^\circ\text{C}$ . On the one hand, the treatment in  $\text{O}_2$  at  $200^\circ\text{C}$  was not efficient enough to restore significantly the activity over deactivated  $\text{CuO}/\text{Cryptomelane}$ , attributed to the large

stability of the inactive resulting  $\text{Mn}_3\text{O}_4$  and  $\text{CuMnO}_4$  phases. Hence, it was necessary to increase the pre-treatment temperature up to  $400^\circ\text{C}$  to achieve sufficient reactivation, but at the same time, the catalyst suffered from  $\text{CuO}$  sintering and crystalline reorganization.

**8.** Surprisingly, and as a rare feature of  $\text{CuO/Cryptomelane}$ , the operation in  $\text{CO-PROX}$  real conditions, comprising  $\text{CO}_2+\text{H}_2\text{O}$  introduction in the reactant mixture led to an improved stability with regards to the more simple  $\text{CO} + \text{O}_2 + \text{H}_2$  conditions. Therefore, with these settings including  $\text{CO}_2+\text{H}_2\text{O}$ , inhibitors considered universally detrimental for the catalytic activity in  $\text{CO-PROX}$  reaction,  $\text{CuO/Cryptomelane}$  exhibits, contrarily, an improved stability and catalytic activity once reached stationary performance after several catalytic cycles, which is a unique feature of this material and results very interesting from a practical point of view.

**9.** The improved performance of  $\text{CuO/Cryptomelane}$  catalyst in the  $\text{CO-PROX}$  mixture containing  $\text{CO}_2+\text{H}_2\text{O}$  elements was studied by means of different techniques that revealed that co-addition of these species largely increased chemisorption of both  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . Specifically, improving  $\text{H}_2\text{O}$  retention is relevant for the case of hydrophobic  $\text{CuO/Cryptomelane}$  material, since water molecules may be hosted in the intrachannel structure providing structure reinforcement while balancing forward oxidized states of manganese in the mixed potassium – ( $\alpha\text{-MnO}_2$ ) crystals.

**10.** Mechanistic studies on  $\text{CuO/Cryptomelane}$  catalyst based on non-conventional techniques have presented relevant conclusions with important similarities with those well-reported for  $\text{CuO/CeO}_2$  catalyst, such as: (1) the participation of lattice oxygen in the  $\text{CO-PROX}$  reaction following MVK-type mechanism; (2) the identification of the  $\text{CO}$  oxidation reaction site in the partially reduced  $\text{Cu}$  species in the labile  $\text{Cu} - \text{O} - \text{Mn}$  bridges, as in  $\text{Cu} - \text{O} - \text{Ce}$  for  $\text{CuO/CeO}_2$ ; (3) the role of the support in the assistance on the regeneration of lattice oxygen.

**11.** The excellent activity and stability of  $\text{CuO/CeO}_2$  catalysts is not found for  $\text{CuO/Cryptomelane}$ , since  $\text{Cryptomelane}$  support is not so active at facilitating oxygen to  $\text{Cu}_x\text{O}$  particles, as demonstrated by a poorer oxygen exchange capacity by isotopic pulse experiments. Hence, reduction – reoxidation processes in  $\text{CO-PROX}$  reaction course remain imbalance and eventually lead to an average reduction with irreversible consequences on the activity of  $\text{CuO/Cryptomelane}$ .

**12.** Finally, as a proof of concept, 3D printing has been used to prepare a honeycomb-like cordierite monolith with asymmetrical channels that improves the performance of conventional honeycomb catalyst supports. 3D-printing technology overcomes the limitations of conventional manufacture

procedures based on extrusion and gives higher freedom in the design of monolith supports with complex shapes. Provided that the study was focused on the effect of monolith support design with complex shapes on the catalytic activity in CO-PROX reaction, CuO/CeO<sub>2</sub> catalyst was chosen as active phase in order to skip the complicated stability considerations inherent to CuO/Cryptomelane catalyst. Channels section of the improved asymmetrical monolith are larger at the reactants entrance side than in the exit side, improving with regard to conventional monoliths both the reaction rate, when reaction behaves under kinetic rate control, and the radial diffusion of reactants, when reaction behaves under external gas diffusion rate control.

## Introducción general

### Actual problemática medioambiental

Actualmente vivimos en un mundo dinámico en pleno desarrollo industrial y tecnológico en el que las grandes potencias establecidas y los países emergentes consumen cada año más energía, principalmente obtenida a partir de combustibles fósiles (petróleo, carbón, gas natural), a pesar de que su uso lleva asociados una multitud de problemas. En primer lugar, la quema de estos recursos produce cantidades incontroladas de CO<sub>2</sub>, gas involucrado en el calentamiento global a través del *efecto invernadero*. Pese a los compromisos internacionales y una mayor concienciación política, la emisión de CO<sub>2</sub> no deja de aumentar año tras año, lo que es origen de una severa preocupación medioambiental<sup>[1, 2]</sup>. En segundo lugar, la producción de contaminantes atmosféricos como NO<sub>x</sub>, VOCs o SO<sub>2</sub>, suma una importante problemática adicional asociada al uso de estos recursos, por los perjuicios que ocasionan en el medioambiente y en la salud de las personas.

Además de ello, debido a la irregular distribución de las reservas mundiales de combustibles fósiles se ha gestado una sólida dependencia energética hacia las potencias sustentadoras de estos recursos condicionando el panorama de desarrollo económico internacional. Y si se considera el hecho de que estas reservas se irán agotando, esta situación de dependencia puede desencadenar una grave crisis energética si no se perfeccionan soluciones alternativas a tiempo.

### Hidrógeno como vector energético

Así pues, ante unos pronósticos que vaticinan un importante incremento de la demanda energética a nivel mundial en las próximas décadas, la búsqueda de formas de obtención de energía sostenible se convierte en un objetivo de prioridad máxima. En este contexto de exploración, el hidrógeno ha sido señalado por parte de la comunidad científica como la alternativa capaz de sustituir a los combustibles fósiles y generar la mayor parte de la energía del futuro, ya sea mediante combustión, o como alimentación a dispositivos electroquímicos especiales, como las pilas de combustible de membrana de intercambio protónico (*Proton Exchange Membrane fuel cell*, PEMFC).

Los argumentos que refuerzan esta tesis se basan en su alta exotermicidad de combustión, que lo convierte en el combustible de mayor capacidad de almacenamiento por unidad de masa. Idealmente, se podrían satisfacer las demandas energéticas de forma inextinguible, eficiente, libre de emisiones contaminantes y con un coste razonable, si se lograra superar las limitaciones actuales en la producción, almacenamiento y distribución de H<sub>2</sub><sup>[3]</sup>. Pero, aun siendo el elemento más abundante del universo, en nuestro planeta el H se encuentra siempre combinado con otros átomos como C, O ó N, y no en forma de gas diatómico, por lo que se precisa irremediablemente de un método por el cual se obtenga a partir de otras fuentes. Es por ello por lo que no se considera al H<sub>2</sub> como una fuente de energía, sino como un *vector energético*.

## Rutas de producción y purificación de hidrógeno

De las opciones que se conocen para sintetizar hidrógeno, la electrólisis del agua es la ruta más limpia y la que produce un H<sub>2</sub> de más alta pureza, pero requiere del suministro de una gran cantidad de energía eléctrica, y el proceso no es ventajoso todavía sin el apropiado desarrollo de las energías renovables<sup>[4]</sup>. De ser posible su implantación extendida, se obtendría H<sub>2</sub> muy puro mediante un proceso completamente respetuoso con el medio ambiente. Sin embargo, hasta la fecha prácticamente la totalidad del H<sub>2</sub> producido procede de combustibles fósiles, y su uso lleva asociado una co-producción de CO<sub>2</sub> importante<sup>[5,6]</sup>. Aun así, se puede actuar capturando esas emisiones localizadas de forma eficiente para su almacenamiento y posterior transformación, con el fin de garantizar un proceso neto medioambientalmente muy sostenible<sup>[7,8]</sup>. A día de hoy, el método de producción de H<sub>2</sub> más empleado es el reformado de hidrocarburos con vapor de agua, por ser el más barato, a pesar de ser el método que más impacto medioambiental supone<sup>[1,3,9]</sup>.

En la búsqueda de soluciones a corto-medio plazo en relación a los aspectos de su producción, hasta la rentabilidad de la electrólisis del agua, se pretende optimizar la eficiencia y reducir el impacto medioambiental de los métodos actuales para producir H<sub>2</sub>, que emplean hidrocarburos como precursor. De entre ellos, el más extendido es el reformado con vapor (*Steam Reforming*, SR), reacción (1)<sup>[3,10-13]</sup>:

Como se expresa en la reacción (1), la producción de H<sub>2</sub> viene acompañada de un 10-15% de CO, mezcla conocida como *gas de síntesis*, intermediario en la generación de productos de gran importancia industrial, entre otros usos destacados. Sin embargo, cuando se tiene interés en la obtención de H<sub>2</sub> puro, este subproducto debe ser eliminado, por ejemplo, en la síntesis del amoníaco o en las PEMFC, cuyo electrocatalizador (Pt/C) se envenena con la presencia de CO. En estos casos, se requiere de etapas subsiguientes a la de reformado para la eliminación del CO hasta un nivel de tolerancia establecido<sup>[10-14]</sup>.

En este sentido, a la reacción de reformado le sigue otra etapa catalítica conocida como reacción de desplazamiento de agua (*Water Gas Shift reaction*, WGS), reacción (2).

Con ella, se reduce el CO en dos etapas, a alta temperatura (HTWGS) y a más baja temperatura (LTWGS) hasta un pequeño porcentaje en volumen de mezcla, y se incrementa la concentración de combustible. A la salida del reactor de WGS, la composición típica en volumen del caudal de salida es cercana al 0.5-1% de CO, pero aún así, ese pequeño porcentaje de CO afecta negativamente al funcionamiento de la PEMFC debido a la quimisorción preferente de CO sobre el Pt electrodico<sup>[15]</sup>. Es por ello que el procedimiento requiere de una etapa adicional de purificación en la que se reduzca hasta la cantidad permitida de 10 ppm de CO la alimentación a la pila<sup>[14]</sup>.

Para este propósito, existen 2 vías: (i) separación física del H<sub>2</sub>, mediante procedimientos como la separación criogénica, adsorción a presión oscilante (*Pressure Swing Adsorption*, PSA), o la difusión selectiva, y (ii) transformación catalítica de CO, a CH<sub>4</sub> (*Selective Methanation*, SMET) o a CO<sub>2</sub> (*Preferential Oxidation*, PROX CO). De ellos, la ruta catalítica es la más conveniente para aplicaciones portátiles o a pequeña escala<sup>[10,11,13,14]</sup>. Ambos procedimientos, SMET y PROX CO han demostrado eliminar satisfactoriamente el CO residual del flujo de salida del reactor WGS. No obstante, de entre ellos, la oxidación preferente de CO es el más destacado, debido a un menor consumo no deseado de H<sub>2</sub> (menor pérdida eficiencia para la pila) aun siendo más difícil de ejecutar, dada la mayor exotermicidad de la reacción de oxidación y la necesidad de inyección controlada de un caudal supletorio de oxidante<sup>[6,16]</sup>.

### Reacción de Oxidación Preferente de CO (CO-PROX)

La reacción de PROX CO ha sido ampliamente estudiada debido a su gran interés. El aspecto más significativo es la reacción selectiva de un componente minoritario de la mezcla gaseosa (CO) frente a altas concentraciones de H<sub>2</sub>, siendo ambos susceptibles de oxidarse, por lo que el desarrollo de un catalizador apropiado que se ajuste a las exigencias del proceso es indispensable. Así, las reacciones implicadas vienen descritas según las reacciones 3 y 4:

Ambas reacciones son competitivas por el oxígeno suministrado, siendo la reacción (3) la única que interesa que suceda idealmente, puesto que la reacción (4) supone un consumo de H<sub>2</sub> (combustible de la pila). Adicionalmente, también pueden ocurrir en las condiciones de operatividad otras reacciones paralelas que pueden repercutir en la eficiencia neta del proceso, como la reacción WGS (2); reacción inversa WGS (RWGS), (5); metanación del CO, (6); o de CO<sub>2</sub><sup>[3,11]</sup>:

En este escenario, los catalizadores adecuados para su uso en la reacción de PROX CO deben cumplir una serie de requisitos:

1. Alta actividad en la oxidación de CO.
2. Alta selectividad frente a la reacción de oxidación de H<sub>2</sub>.
3. Operatividad en el rango de temperaturas conveniente (típicamente 80-200°C), limitado por los procesos de WGS y el funcionamiento de la pila PEMFC.
4. Resistencia a la desactivación por H<sub>2</sub>O y CO<sub>2</sub>.

### Catalizadores para la reacción CO-PROX: estado del arte

El extenso trabajo realizado en este campo, ha concluido hasta ahora con grandes avances, desarrollando catalizadores de diversa índole con un buen

funcionamiento. En términos generales, se trata de catalizadores metálicos soportados con características particulares, que varían en base al tipo de metal, naturaleza del soporte, contenido metálico, y las condiciones de preparación. De la amplia gama que se puede encontrar en la bibliografía científica, se pueden agrupar fundamentalmente en 3 categorías, según el metal.

*Catalizadores basados en metales nobles*<sup>[17,18]</sup>. Siendo los más estudiados Pt<sup>[19,20]</sup>, Pd<sup>[21,22]</sup>, Ru<sup>[23,24]</sup> y Rh<sup>[25]</sup>, soportados en Al<sub>2</sub>O<sub>3</sub>, SiO<sub>2</sub> y otros soportes tales como zeolitas u óxidos metálicos, así como también algunas combinaciones bimetalicas<sup>[26-28]</sup>. Con carácter general, estos sistemas reducen el CO hasta los límites demandados, y operan bien bajo la presencia de H<sub>2</sub>O y CO<sub>2</sub>. Como inconvenientes, destacan su moderada selectividad y su alto precio, lo que frena su uso generalizado.

*Catalizadores basados en oro*<sup>[29-31]</sup>. Habiéndose empleado distintos soportes como TiO<sub>2</sub><sup>[32]</sup>, Fe<sub>2</sub>O<sub>3</sub><sup>[33,34]</sup>, CeO<sub>2</sub><sup>[35]</sup>, ó MnO<sub>2</sub><sup>[36]</sup>, entre otros muchos, los resultados son dispares y altamente dependientes del procedimiento experimental de preparación. A grandes rasgos se puede afirmar que estos catalizadores presentan una alta actividad catalítica, por lo que trabajan a temperaturas más bajas que los anteriores, pero como limitación importante, se desactivan fácilmente en presencia de la mezcla de H<sub>2</sub>O y CO<sub>2</sub>.

*Catalizadores basados en metales de transición*<sup>[37]</sup>. Liderando este grupo se encuentra indudablemente el sistema formado por óxido de cobre y óxido de cerio (CuO-CeO<sub>2</sub>) en sus diversas configuraciones<sup>[38-45]</sup>. Este conjunto presenta unas propiedades catalíticas excelentes debido a la fuerte interacción sinérgica metal-soporte sin suponer un excesivo coste, por lo que actualmente centra múltiples campos áreas de investigación en catálisis.

### Propiedades del sistema CuO/CeO<sub>2</sub>

En el caso de la ceria, la semirreacción del par redox Ce<sup>3+</sup> ↔ Ce<sup>4+</sup> ocurre con mucha facilidad en su estructura típica de fluorita, lo que contribuye a una gran movilidad de oxígeno en la red cristalina, y la capacidad de adsorber reversiblemente oxígeno para suministrarlo de forma modulada a sustrato reactivo, que se conoce de forma genérica como *capacidad de almacenamiento de oxígeno*. Este óxido parcialmente reducible mejora sus propiedades catalíticas en gran medida cuando se le incorporan pequeños porcentajes de Cu, debido a procesos redox que ocurren entre el soporte y la fase dispersa, que se maximizan con el mayor contacto interfacial<sup>[43-45]</sup>. Así, debido al gran interés que despierta este tipo de catalizadores, se han publicado múltiples estudios relativos a su caracterización detallada en base al método de preparación, contenido metálico o el dopaje con otros iones, y el efecto que ejercen dichos factores en su actividad catalítica para diversas reacciones<sup>[37, 44, 46, 47]</sup>. Para la reacción de PROX CO y en particular para el tándem óxido de cobre-óxido de cerio, se han obtenido excelentes resultados en trabajos anteriores, y se ha realizado un análisis mecanístico muy completo como el de Martínez-Arias et al.<sup>[39]</sup> o Polster et al.<sup>[45]</sup>. En ellos, se ha concluido que el mecanismo transcurre a través de reacciones redox que afectan tanto al Cu (mayoritariamente presente como CuO) como al

---

soporte, en un sistema en el que la reducibilidad de cada uno de ellos está favorecida por la presencia del otro componente<sup>[48]</sup>. Dicha reducibilidad es beneficiosa para la reacción tanto en términos de selectividad como de conversión, formando grupos  $\text{Cu}^+$  superficiales en la interfase metal-soporte, que se han descrito como los sitios activos para la adsorción de CO, preferente sobre la adsorción disociativa de  $\text{H}_2$ .

### **Criticalidad de los sistemas dependientes de Ce y motivación del proyecto**

No obstante, pese a los prometedores resultados que se han alcanzado para estos catalizadores, existe un problema fundamental de carácter estratégico que se ha de considerar antes de implantar a gran escala estos sistemas: la dificultad de la extracción y producción en masa de las tierras raras, como el Ce. Aunque las menas de este grupo de elementos es bien dispersa en la Tierra, actualmente China es el principal productor, con el 95% de mercado. Debido a la escasa concentración relativa de estos recursos en la mayor parte del mundo, no resulta rentable asumir las altas inversiones para su extracción, por lo que la comunidad internacional ha optado por importarlo del principal proveedor, concediendo a China una posición muy favorecedora de la que el país está siendo beneficiado por el auge del uso de estos elementos. Así pues, dispuestos a abandonar una dependencia energética de los países con reservas de petróleo o gas natural, pasar a la economía del hidrógeno empleando estos catalizadores supondría someterse a otro yugo, del que las políticas actuales son conscientes y pretenden evitar a toda costa. Es por ello que cada vez se mira más hacia un horizonte libre de tierras raras, en el que otros materiales igualen (o superen) sus magníficas prestaciones en el ámbito tecnológico y catalítico.

La motivación de este trabajo es encontrar un sustituto apropiado de la ceria como soporte para catalizar la reacción de PROX CO, a partir de una aproximación a su química especial utilizando óxidos parcialmente reducibles como los  $\text{MnO}_x$ , quienes, debido a sus múltiples estados de oxidación y posibilidad de formación de óxidos mixtos, su abundancia natural y su reducido coste, son unos candidatos muy prometedores<sup>[49, 50]</sup>. Estos materiales se han probado como catalizadores y soportes de catalizadores para reacciones de oxidación de diversa índole en publicaciones precedentes<sup>[51-54]</sup>, así como en la reacción de PROX CO<sup>[55-57]</sup>, mostrando unos resultados muy positivos, pero lejos de superar a los óxidos de cerio.

En este punto, cabe destacar que la mezcla natural de óxidos Cu-Mn denominada popularmente *hopcalita*, ha venido empleándose ampliamente desde hace décadas para la oxidación de CO en sistemas de protección respiratorios en minería, campo militar y dispositivos espaciales<sup>[58,59]</sup>, lo que ha inspirado estas investigaciones y conducido al estudio en profundidad de estos catalizadores. Así, además de ello, los  $\text{MnO}_x$  despiertan un gran interés gracias a la versatilidad de estos óxidos para formar distintas estructuras cristalinas organizadas, lo que permite sintetizar arquitecturas tridimensionales especiales, que ayuden a mejorar sus propiedades catalíticas<sup>[60,61]</sup>.

En este contexto, el material en el que se ha centrado la atención de este trabajo es el óxido mineral de manganeso *criptomelano*, cuyo nombre deriva de las palabras en griego “negro” y “oculto”, con el que se le bautizó debido a su tardía identificación dentro de la mezcla de minerales conocida como *psilomelano*<sup>[62]</sup>. Se trata de una especie natural con fórmula no estequiométrica  $K_xMn_8O_{16}$  y estructura definida en túneles formados por la unión de 2x2 octaedros de  $MnO_6$  ocupados parcialmente por cationes potasio, pero existen procedimientos para sintetizar en laboratorio óxidos con la misma estructura y composición denominados de forma genérica por sus siglas en inglés K-OMS-2, o simplemente, OMS-2 (*Octahedral Molecular Sieves, 2x2*)<sup>[63-65]</sup>.

Como características de este material, cabe destacar su desarrollada microporosidad con distribuciones relativamente estrechas de tamaño de poro alrededor de  $0.46 \times 0.46 \text{ nm}$ <sup>[66]</sup>, y un estado de oxidación mixto, en promedio estimado en 3.8 consecuencia de la presencia mayoritaria en la red de cationes  $Mn^{4+}$ , junto con  $Mn^{3+}$  y en menor proporción  $Mn^{2+}$ . Esta variabilidad en el estado de oxidación, junto con su estructura ordenada le otorga una capacidad de intercambio iónico y una alta movilidad de oxígeno lábil en la red cristalina, lo que recuerda en cierto sentido a las propiedades de la ceria<sup>[67]</sup>.

Así, los óxidos tipo criptomelano se han estudiado en profundidad durante las dos últimas décadas, por su gran versatilidad en catálisis para reacciones importantes en el ámbito medioambiental y en el energético, como la oxidación de compuestos orgánicos, y la oxidación de CO, entre otras<sup>[64, 68-75]</sup>. La principal ventaja de este material es que puede ser diseñado incluyendo modificaciones en el procedimiento de síntesis para adoptar una forma concreta, superficie específica, porosidad, o composición requeridos<sup>[68, 76]</sup>. De forma general, la incorporación a esta estructura de metales activos conduce a mejoras importantes en todas sus aplicaciones, siendo los procedimientos más reportados aquéllos que introducen  $Ag^+$ <sup>[68, 77, 78]</sup> o  $Cu^{2+}$ <sup>[79-85]</sup>, por ser los que han aportado resultados más prometedores. Dichas modificaciones dependen del método en el que se haya incorporado el agente dopante, pudiendo ser sólo depositado sobre la superficie del criptomelano, sustituyendo a las especies de potasio dentro de los túneles o reemplazando a iones de Mn constituyentes de los octaedros, multiplicando las posibilidades y las características de los materiales preparados<sup>[81]</sup>.

## Objetivos generales del trabajo

Teniendo en cuenta la contextualización general expuesta, este Proyecto de Tesis surge tiene como principal objetivo la exploración de catalizadores activos con formulaciones sostenibles para la reacción de Oxidación Preferencial de CO (CO-PROX), que es un paso crítico hacia la purificación exhaustiva de  $H_2$  procesado con las actuales tecnologías de producción.

Con el objetivo de evitar la costosa utilización de metales nobles y la limitada estabilidad característica de los catalizadores de oro, este Proyecto de Tesis aborda el estudio de catalizadores basados en óxido de cobre como una opción rentable y eficiente para llevar a cabo la reacción CO-PROX. Como primer

---

enfoque, se han estudiado los sistemas de CuO/CeO<sub>2</sub> convencionales para establecer un conocimiento fundamental de base utilizando un catalizador con una reconocida excelente actividad. A partir de ello, los resultados de la investigación fundamental con el catalizador de CuO/CeO<sub>2</sub> se establecen como punto de referencia en la consideración de su posible sustitución por catalizadores de óxido de cobre y óxido de manganeso alternativos, medioambientalmente mucho más compatibles, a saber, las formulaciones de CuO/Criptomelano.

Por lo tanto, los principales objetivos establecidos en este Proyecto de Tesis se pueden sintetizar en los siguientes cinco puntos generales:

**1-** *El estudio fundamental sobre los sistemas de CuO/CeO<sub>2</sub> para la evaluación de las características y propiedades físico-químicas que resultan en su sobresaliente actividad como catalizadores CO-PROX.*

De acuerdo a la estructura en la que se ha estructurado esta Tesis, el Objetivo n. 1 se trata en los Capítulos 3 y 4, que comprenden estudios mecanísticos de CO-PROX sobre catalizadores de CuO/CeO<sub>2</sub> puros y dopados, respectivamente.

**2-** *La preparación, caracterización y evaluación de la actividad de catalizadores CO-PROX soportados en óxidos metálicos alternativos al óxido de cerio, siendo en concreto enfocado el estudio sobre el sistema particular CuO/Criptomelano.*

En este sentido, el objetivo n. 2 se aborda principalmente a lo largo de los Capítulos 5 y 6, con el estudio sistemático de la estabilidad de CuO/Criptomelano y los problemas de regeneración en condiciones de operación CO-PROX, incluida la simulación de en condiciones reales de operación.

**3-** *La propuesta de un estudio mecanístico consistente sobre la reacción de CO-PROX con el catalizador alternativo CuO/Criptomelano, en analogía con los fundamentos establecidos a partir de los sistemas de CuO/CeO<sub>2</sub>.*

Con el objetivo de abordar el objetivo n. 3, el Capítulo 7 comprende el uso de métodos sofisticados no convencionales para el estudio de problemas mecanísticos de CO-PROX en catalizadores de CuO/Criptomelano, dadas las limitaciones intrínsecas de las técnicas convencionalmente extendidas para este fin en su aplicación a este particular material.

**4-** *La comparación crítica entre los catalizadores de CuO/CeO<sub>2</sub> y CuO/Criptomelano en la aplicación de CO-PROX, en términos de actividad y estabilidad en diversas condiciones de reacción, incluida la presencia de inhibidores de CO<sub>2</sub> y H<sub>2</sub>O.*

Respecto al objetivo n. 4, el Capítulo 8 recopila resultados más relevantes de los catalizadores de CuO/CeO<sub>2</sub> y CuO/Criptomelano para su evaluación comparativa directa.

**5-** *La escalabilidad de las fases activas en polvo en base de óxido de cobre a catalizadores monolíticos de tamaño mediano con actividad mejorada preparados por medio de la tecnología de impresión 3D.*

En última instancia, el objetivo n. 5 comprende un salto tecnológico que se traslada el proceso catalítico desde la pequeña escala de los catalizadores en polvo hasta el soporte de monolito, que además se realiza bajo un enfoque muy novedoso mediante impresión 3D, como se presenta en el Capítulo 9.

## Resultados y conclusiones más relevantes

(1) A partir de estudios mecanísticos sobre catalizadores de  $\text{CuO/CeO}_2$  en la reacción CO-PROX, se puede concluir que la velocidad de oxidación del CO con catalizadores de óxido de cobre-óxido de cerio se correlaciona con la formación del carbonilo  $\text{Cu}^+ \text{-CO}$ . Sin embargo, la desorción de los productos de carbono formados en la superficie de la ceria es el paso más lento por debajo de cierto umbral de temperatura, con lo que la química superficial juega un papel fundamental. Particularmente, los grupos hidroxilo desempeñan un papel clave en la determinación de la naturaleza de los intermedios basados en carbono formados por la quimisorción y oxidación de CO, cuya abundancia depende de las características redox de los catalizadores basados en  $\text{CuO/CeO}_2$ . Esencialmente, los hidroxilos favorecen la formación de bicarbonatos con respecto a los carbonatos, y los catalizadores que forman más bicarbonatos alcanzan velocidades de oxidación de CO más rápidas que los que favorecen a los carbonatos. Todos los catalizadores basados en  $\text{CuO/CeO}_2$  probados mostraron una buena actividad catalítica en la reacción CO-PROX, aunque la presencia de dopantes (20% at.) en la red de ceria produjo en general un efecto perjudicial sobre la óptima actividad de  $\text{CuO/CeO}_2$  puro.

(2) El mineral Criptomelano es un material abundante, no tóxico, con una preparación sintética de laboratorio escalable, fácil y reproducible que presenta oportunidades prometedoras como catalizador activo para la oxidación de CO y la reacción de CO-PROX. Las propiedades fisicoquímicas del soporte Criptomelano, con su alta movilidad de oxígeno y lábil ciclo redox entre los diferentes estados de oxidación de Mn, recuerdan ligeramente a las de la  $\text{CeO}_2$ , con una capacidad de almacenamiento de oxígeno (OSC) bien conocida en el intercambio electrónico rápido entre los pares  $\text{Ce}^{3+}/\text{Ce}^{4+}$ , por lo que se postula como un candidato prometedor para sustituir algunos de los sistemas catalíticos basados en  $\text{CeO}_2$ .

(3) En la misma línea, cuando el Criptomelano se dopa con óxido de cobre, conforme a las formulaciones de  $\text{CuO/Criptomelano}$ , la actividad catalítica en la reacción CO-PROX se mejora en gran medida debido a la promoción de sus propiedades redox, a partir de la formación de entidades  $\text{Cu-O-Mn}$ , dando lugar a grupos de oxígeno lábiles con buena interacción con moléculas de CO reactivas.

(4) Sin embargo, la actividad mejorada de  $\text{CuO/Criptomelano}$  con respecto a Criptomelano es contrarrestada con una pérdida importante de estabilidad y una desactivación significativa al cabo de los ciclos catalíticos de reacción de CO-PROX. El estudio sobre los mecanismos de desactivación de  $\text{CuO/Criptomelano}$  ha concluido que la microestructura básica de Criptomelano, configurada a partir

---

de nano-túneles bien definidos ( $\alpha$ - $\text{MnO}_2$ ), colapsa parcialmente dando lugar a las fases inactivas  $\text{Mn}_3\text{O}_4$  y  $\text{CuMn}_2\text{O}_4$  cristalino, lo que implica una reducción en promedio de manganeso y cobre con respecto al estado inicial del catalizador. Por lo tanto, la promoción redox con el depósito de Cu en CuO/Criptomelano resulta positiva para la actividad catalítica en la reacción CO-PROX, gobernada por un mecanismo tipo MVK, pero al mismo tiempo, su mayor labilidad hacia la reducción hace que la abstracción de oxígeno de red sea demasiado fácil, haciendo que el catalizador CuO/Criptomelano quede finalmente reducido y desactivado.

(5) En base a las estrategias de regeneración que se pueden establecer en este sentido, se han estudiado tratamientos previos de reoxidación en atmósferas de  $\text{O}_2$  a diferentes temperaturas:  $200^\circ\text{C}$  y  $400^\circ\text{C}$ . Se ha constatado que, por un lado, el tratamiento en  $\text{O}_2$  a  $200^\circ\text{C}$  no resulta suficientemente eficaz como para restablecer significativamente la actividad sobre CuO/Criptomelano desactivado, debido a la gran estabilidad de las fases inactivas resultantes de  $\text{Mn}_3\text{O}_4$  y  $\text{CuMn}_2\text{O}_4$ . Por lo tanto, fue necesario aumentar la temperatura del pretratamiento hasta  $400^\circ\text{C}$  para lograr una reactivación suficiente, pero al mismo tiempo, el catalizador sufrió de la sinterización de CuO y reorganización cristalina.

(6) Sorprendentemente, y como una característica genuina del catalizador CuO/Criptomelano, el uso condiciones de reacción reales CO-PROX, que incluye la introducción de  $\text{CO}_2 + \text{H}_2\text{O}$  en la mezcla de reactivos, supone una estabilidad mejorada con respecto a las condiciones más simples de  $\text{CO} + \text{O}_2 + \text{H}_2$  comúnmente utilizadas. Asimismo, en estas condiciones con adición de los inhibidores  $\text{CO}_2 + \text{H}_2\text{O}$ , considerados universalmente perjudiciales para la actividad catalítica en la reacción CO-PROX, CuO / Criptomelano exhibe, por el contrario, una estabilidad y una actividad catalítica mejoradas una vez se alcanza actividad en un estado estacionario después de varios ciclos catalíticos. Ello es, una característica única para este material con implicaciones prácticas altamente interesantes.

(7) La actividad mejorada del catalizador de CuO/Criptomelano en la mezcla de CO-PROX compuesta con  $\text{CO}_2 + \text{H}_2\text{O}$  se estudió mediante diferentes técnicas, que han revelado que la adición conjunta de estas especies incrementa en gran medida la quimisorción de  $\text{CO}_2$  y  $\text{H}_2\text{O}$ . Específicamente, el incremento en la retención de  $\text{H}_2\text{O}$  es un hecho relevante para el caso del catalizador hidrofóbico CuO/Criptomelano, ya que las moléculas de agua se pueden incorporar dentro de los microtúneles proporcionando reforzando la estructura y se equilibrando los estados oxidados de manganeso.

(8) Los estudios mecanísticos sobre el catalizador de CuO/Criptomelano basados en técnicas no convencionales han aportado conclusiones relevantes con importantes similitudes con las bien estudiadas para el caso del catalizador de CuO/ $\text{CeO}_2$ . Por ejemplo, como: (1) la participación de oxígeno de red en la reacción de CO-PROX, siguiendo el mecanismo de tipo MVK; (2) el sitio de reacción identificado para la oxidación de CO, siendo las especies de Cu parcialmente reducidas en los enlaces lábiles interfaciales de Cu - O - Mn, como

en Cu - O - Ce para CuO/CeO<sub>2</sub>; (3) el rol del soporte en la asistencia en la regeneración de oxígeno activo de la red de las partículas de Cu<sub>x</sub>O.

(9) El estudio fundamental presentado en este documento sobre el catalizador de CuO/CeO<sub>2</sub> con el uso de técnicas experimentales altamente sofisticadas y el modelado computacional por DFT ha dilucidado la participación del soporte de CeO<sub>2</sub> en la restitución de oxígeno de la red durante el progreso de la reacción CO-PROX. Según los resultados obtenidos, la restauración de O<sub>2</sub> se lleva a cabo directamente en las especies de CuO cuando están principalmente oxidadas, a bajas temperaturas. A medida que la reacción va teniendo lugar, las partículas se van reduciendo parcialmente Cu<sub>x</sub>O en proceso gradual iniciado localmente en superficie que va propagando la extensión de la reducción hacia el bulk. La aceleración de la oxidación de CO por el aumento de la temperatura conduce a un estado crítico reducido sobre las partículas de Cu<sub>x</sub>O activan la reacción competitiva de oxidación de H<sub>2</sub> que a su vez incrementará importantemente la reducción de Cu<sub>x</sub>O. Sobrepasado cierto punto de reducción, la captación directa de O<sub>2</sub> no es eficaz y se produce preferentemente en el soporte de CeO<sub>2</sub>, que ayuda a la reposición de O en las interfases con actividad de intercambio redox entre Cu - O - Ce. Los experimentos de NAP-XPS en condiciones CO-PROX *operando* evidenciaron una reducción muy superficial en CeO<sub>2</sub> y la naturaleza de dicho evento se ha asociado con la transferencia de oxígeno de la red de la ceria a las partículas de Cu<sub>x</sub>O en el proceso de la restitución de O a través de CeO<sub>2</sub>.

(10) La participación activa del soporte de CeO<sub>2</sub> en el mecanismo de reoxidación del catalizador implica, por lo tanto, varias consideraciones que resultan la actividad mejorada del catalizador CuO/CeO<sub>2</sub> con respecto a cualquier otro catalizador basado en CuO, principalmente debido a una gran reversibilidad en los ciclos de reducción - ciclos de oxidación. En contraposición para el catalizador CuO/Criptomelano, el soporte de Criptomelano no es tan activo para facilitar el oxígeno a las partículas de Cu<sub>x</sub>O, como se ha demostrado en la más limitada capacidad de intercambio de oxígeno mediante los experimentos de pulsos isotópicos. Por ello, los procesos de reducción - reoxidación necesarios para el curso de la reacción CO-PROX están desequilibrados pasado cierto umbral de reducción de Cu<sub>x</sub>O y finalmente conducen a una reducción promedio con consecuencias irreversibles en la actividad de CuO/Criptomelano.

(11) Finalmente, como prueba de concepto, la impresión 3D se ha utilizado para preparar monolitos de cordierita con geometría de canales asimétricos que han mejorado la actividad catalítica con respecto de análogos soportes monolíticos convencionales, sobre los que se depositó la fase activa estudiada en polvo CuO/CeO<sub>2</sub>. En este sentido, la tecnología de impresión 3D supera las limitaciones de los procedimientos de fabricación convencionales basados en la extrusión y aporta gran libertad en el diseño de soportes monolíticos con formas complejas. Así pues, en los monolitos con diseños mejorados, la sección de los canales es mayor en el lado de entrada de los reactivos que en el lado de salida, mejorando con respecto a los monolitos convencionales tanto la velocidad de reacción,

---

cuando la reacción se comporta bajo control cinético, como la difusión radial de los reactivos, cuando la reacción se comporta bajo difusional.

Universidad de Alicante

## Curriculum Vitae

Arantxa Davó Quiñonero was born on the 5<sup>th</sup> July of 1991 in Alicante, Spain. She earned her Bachelor of Science degree in Chemistry from the University of Alicante in 2014, achieving a Graduation with Honorific Mention. After that, she enrolled in her Master Science studies in Materials Science, which was rewarded with an Extraordinary Distinction Prize in 2015. That year, she was awarded with a FPU grant from the Spanish Ministry of Education and started her PhD studies in the Inorganic Chemistry Department of the University of Alicante. This Doctoral Thesis describes the most important findings of the research she conducted in the study of the catalytic CO clean-up in the purification of H<sub>2</sub> by means of the Preferential Oxidation of CO (CO-PROX reaction).

## List of Publications

- 1. Role of hydroxyl groups in the preferential oxidation of CO over copper oxide-cerium oxide catalysts.**  
A. Davó-Quiñonero, M. Navlani-García, D. Lozano-Castelló, A. Bueno-López, J. Anderson.  
*ACS Catalysis*, **6(3)** (2016) 1723-1731.
- 2. CuO/Cryptomelane catalyst for preferential oxidation of CO in the presence of H<sub>2</sub>: deactivation and regeneration.**  
A. Davó-Quiñonero, M. Navlani-García, D. Lozano-Castelló, A. Bueno-López.  
*Catalysis Science & Technology*, **6(14)** (2016) 5684-5691.
- 3. Rapid-scan operando infrared spectroscopy.**  
A. Davó-Quiñonero, A. Bueno-López, D. Lozano-Castelló, A.J. McCue, J. Anderson. *ChemCatChem* **8(11)** (2016) 1905-1908.
- 4. Unexpected stability of CuO/Cryptomelane under Preferential Oxidation of CO reaction conditions in the presence of CO<sub>2</sub> and H<sub>2</sub>O.**  
A. Davó-Quiñonero, D. Lozano-Castelló, A. Bueno-López.  
*Applied Catalysis B: Environmental* **217** (2017) 459-465.
- 5. Improved CO Oxidation Activity of 3DOM Pr-Doped Ceria Catalysts: Something Other Than an Ordered Macroporous Structure.**  
A. Davó-Quiñonero, J. González-Mira, I. Such-Basáñez, J. Juan-Juan, D. Lozano-Castelló, A. Bueno-López. *Catalysts* **7(2)** (2017) 67-79

6. **Templated Synthesis of Pr-Doped Ceria with Improved Micro and Mesoporosity Porosity, Redox Properties and Catalytic Activity.**  
A. Davó-Quñonero, J. González-Mira, I. Such-Basáñez, D. Lozano-Castelló, A. Bueno-López. *Catalysis Letters* **148**(1) (2018) 258-266.
7. **Macroporous carrier-free Sr-Ti Catalyst for NO<sub>x</sub> Storage and Reduction.**  
V. Alcalde-Santiago, A. Davó-Quñonero, I. Such-Basáñez, D. Lozano-Castelló, A. Bueno-López. *Applied Catalysis B: Environmental* **220** (2018) 524-532.
8. **On the soot combustion mechanism using 3DOM ceria catalysts.**  
V. Alcalde-Santiago, A. Davó-Quñonero, I. Such-Basáñez, D. Lozano-Castelló, A. Bueno-López. *Applied Catalysis B: Environmental* **234** (2018) 187-197.
9. **Three-dimensionally ordered macroporous PrOx: an improved alternative to ceria catalysts for soot combustion.**

DOI: 10.1016/j.apcatb.2018.10.049
10. **Improved asymmetrical honeycomb monolith catalyst prepared using a 3D printed template.**  
A. Davó-Quñonero, D. Sorolla-Rosario, E. Bailón-García, D. Lozano-Castelló, A. Bueno-López. *Journal of Hazardous Materials* **368** (2019) 638-643
11. **PrOx catalysts for the combustion of soot generated in diesel engines. Effect of CuO and 3DOM structure.**  
V. Alcalde-Santiago, E. Bailón-García, A. Davó-Quñonero, D. Lozano-Castelló, A. Bueno-López. *Catalysis Science & Technology* (2019). DOI: 10.1039/C9CY00130A.
12. **Effect of metal loading on the CO<sub>2</sub> methanation: A comparison between alumina supported Ni and Ru catalysts.**  
A. Quindimil, U. De-la-Torre, B. Pereda-Ayo, A. Davó-Quñonero, E. Bailón-García, D. Lozano-Castelló, J. A. González-Marcos, A. Bueno-López, J. R. González-Velasco. *Catalysis Today* (2019). DOI: 10.1016/j.cattod.2019.06.027

## Contributions to conferences

### ❖ ORAL COMMUNICATIONS

1. **Mechanisms in the catalytic soot combustion with 3-Dimensionally Ordered Macroporous (3DOM) ceria catalysts.**  
Alcalde-Santiago, V., Davó-Quíñonero, A., Lozano-Castelló, D., Bueno-López, A.  
XXVI Spanish American Catalysis Conference (CICat 2018). INTERNATIONAL.  
Celebrated in Coimbra (Portugal) from 09/09/2018 to 14/09/2018.
2. **Surface development of CeO<sub>2</sub> as a redox support in Ru/CeO<sub>2</sub> catalysts towards CO<sub>2</sub> methanation.**  
Quindimil, A., De-la-Torre, U., Pereda-Ayo, B., González-Marcos, J.A., Alcalde-Santiago, V., Davó-Quíñonero, A., Lozano-Castelló, D., Bueno-López, A. González-Velasco, J. R.  
XXVI Spanish American Catalysis Conference (CICat 2018). INTERNATIONAL.  
Celebrated in Coimbra (Portugal) from 09/09/2018 to 14/09/2018.
3. **Ni/LnOx catalysts (Ln = La, Ce or Pr) for CO<sub>2</sub> methanation.**  
Alcalde-Santiago, V., Davó-Quíñonero, A., Lozano-Castelló, D., Quindimil, A., De-la-Torre, U., Pereda-Ayo, B., González-Marcos, J.A., González-Velasco, J. R., Bueno-López, A.  
3rd Fundamentals and applications of cerium dioxide in catalysis. INTERNATIONAL.  
Celebrated in Barcelona (Spain) from 25/06/2018 to 27/06/2018.
4. **Carrier-Free Sr-Ti Catalysts For NOx Storage and Reduction.**  
Alcalde-Santiago, V., Davó-Quíñonero, A., Such-Basáñez, I., Lozano-Castelló, D., Bueno-López, A.  
13th European Congress on Catalysis (Europacat XIII). INTERNATIONAL.  
Celebrated in Florence (Italy) from 27/08/2017 to 31/08/2017.
5. **Improved redox properties and catalytic performance of 3DOM ceria-based catalysts.**  
Davó-Quíñonero, A., González-Mira, J., Such-Basáñez, I., J. Juan-Juan, J., Lozano-Castelló, D., Bueno López, A.  
13th European Congress on Catalysis (Europacat XIII). INTERNATIONAL.  
Celebrated in Florence (Italy) from 27/08/2017 to 31/08/2017.
6. **Macroporous Sr-Ti unsupported catalysts highly efficient towards NOx storage and reduction.**  
Alcalde-Santiago, V., Davó-Quíñonero, A., Such-Basáñez, I., Lozano-Castelló, D., Bueno-López, A.  
Spanish Catalyst Society Conference (SECAT'17). NATIONAL.  
Celebrated in Oviedo (Spain) from 26/06/2017 to 28/06/2017.

7. **DFT study of CO-PROX reaction with copper-based catalysts.**  
Davó-Quíñonero, A., Such-Basáñez, I., Juan-Juan, J., Lozano-Castelló, D., Bueno-López, A.  
Spanish Catalyst Society Conference (SECAT'17). NATIONAL.  
Celebrated in Oviedo (Spain) from 26/06/2017 to 28/06/2017.
8. **CuO/Cryptomelane catalysts as an alternative to CuO/Ceria for CO-PROX reaction.**  
Davó-Quíñonero, A., Lozano-Castelló, D., Bueno-López, A.  
II Young Researchers meeting from Spanish Society of Catalysis. NATIONAL  
Celebrated in Ciudad Real (Spain) from 27/06/2016 to 29/06/2016.
9. **Catalytic soot combustion with strontium titanates prepared through PMMA crystals infiltration.**  
Alcalde-Santiago, V., Davó-Quíñonero, A., Lozano-Castelló, D., Bueno-López, A.  
II Young Researchers meeting from Spanish Society of Catalysis. NATIONAL.  
Celebrated in Ciudad Real (Spain) from 27/06/2016 to 29/06/2016.

#### ❖ POSTER COMMUNICATIONS

1. **On the soot combustion mechanisms using 3DOM ceria catalysts.**  
Alcalde-Santiago, V., Davó-Quíñonero, A., Lozano-Castelló, D., Bueno-López, A.  
3rd Fundamentals and applications of cerium dioxide in catalysis. INTERNATIONAL.  
Celebrated in Barcelona (Spain) from 25/06/2018 to 27/06/2018.
2. **Positive effect of CO<sub>2</sub> and H<sub>2</sub>O with CuO/Cryptomelane catalysts at CO-PROX reaction.**  
Davó-Quíñonero, A., Lozano-Castelló, D., Bueno-López, A.  
Spanish Catalyst Society Conference (SECAT'17). NATIONAL.  
Celebrated in Oviedo (Spain) from 26/06/2017 to 28/06/2017.
3. **Improved redox properties and catalytic activity in ceria-based catalysts with 3-dimensionally-ordered macroporous structure.**  
Davó-Quíñonero, A., González-Mira, J., Such-Basáñez, I., Juan-Juan, J., Lozano-Castelló, D., Bueno-López, A.  
Spanish Catalyst Society Conference (SECAT'17). NATIONAL  
Celebrated in Oviedo (Spain) from 26/06/2017 to 28/06/2017.
4. **Influence of ad-atom nature on the chemisorption of CO on a Cu (111) surface.**  
Davó-Quíñonero, A., Such-Basáñez, I., Juan-Juan, J., Lozano-Castelló, D., Bueno-López, A.  
Abinit hands-on 2017. INTERNATIONAL.  
Celebrated in Bruyeres-le-Chatel, Paris (France) from 30/01/2017 to 03/02/2017.

- 
5. **RhO<sub>x</sub> supported on three dimensionally ordered macroporous ceria for catalytic decomposition of N<sub>2</sub>O.**  
Davó-Quíñonero, A., Fraile-Jiménez, M. I., Lozano-Castelló, D., Bueno-López, A.  
International Thematic Workshop on N<sub>2</sub>O Abatement. INTERNATIONAL.  
Celebrated in Krakow (Poland) from 04/05/2016 to 06/08/2016.
  6. **Copper oxide supported in mixed manganese oxides as catalysts for the selective oxidation of CO.**  
Davó-Quíñonero, A., Navlani-García, M., Lozano-Castelló, D., Bueno-López, A.  
Spanish Catalyst Society Conference (SECAT'15). NATIONAL.  
Celebrated in Barcelona (Spain) from 13/07/2015 to 15/07/2015.
  7. **DRIFTS-MS study in CO-PROX operando conditions using CuO/Ce<sub>0.8</sub>X<sub>0.2</sub>O<sub>2</sub> (X = Ce, Zr, La, Pr, Nd o Ba) catalysts.**  
Davó-Quíñonero, A., Navlani-García, M., Lozano-Castelló, D., Bueno-López, A., Anderson, J. A.  
Spanish Catalyst Society Conference (SECAT'15). NATIONAL.  
Celebrated in Barcelona (Spain) from 13/07/2015 to 15/07/2015.
