A kinetic study for NO catalytic reduction on silica sub-micron diameter tubes

with platinum nanoparticles

ABSTRACT

The selective catalytic reduction (SCR) of NOx with C₃H₆ in the presence of O₂ on silica sub-microtubes with platinum nanoparticles was studied in order to establish a possible reaction mechanism at different experimental conditions. This catalyst showed a high NO conversion with very high selectivity to N₂ at mild conditions in the presence of excess oxygen when using C₃H₆ as reducing agent.

The influence of both NO and C₃H₆ concentrations on their conversions was analyzed at different space times. The obtained results suggest that the three reactants (C₃H₆, NO, and O₂) are adsorbed on Pt sites. The kinetic model proposed considers that both dissociative adsorption of NO and activation of the hydrocarbon can take place simultaneously. Nevertheless, the value of the parameters obtained by the resolution of the model equations indicates that the first one presents a major relevance. These results are in concordance with the high selectivity to N₂ observed, because the preponderance presence of dissociated NO avoids the formation of N₂O by the reaction of molecular NO with N dissociated from NO. Furthermore, both NO reduction and C₃H₆ oxidation conversions are represented reasonably well by the model presented.

1. INTRODUCTION

NO\textsubscript{x} (NO & NO\textsubscript{2}) exhausted from vehicles and stationary combustion engines is one of the important causes of photochemical smog, acid rain, and ozone depletion, which possess serious challenges to human health and environmental protection [1]. Selective catalytic reduction (SCR) technology with hydrocarbons is believed to be one of the most promising options for DeNO\textsubscript{x} [2]. However, SCR usually requires rather high reaction temperature (over 300 °C) when hydrocarbons (HCs) or CO are used as reducing agents [3]. If SCR of NO\textsubscript{x} with HC occurs at low temperature over catalyst with high DeNO\textsubscript{x} activity, the technology could compete with NH\textsubscript{3}-SCR and be more practical for the removal of NO\textsubscript{x} at stationary or mobile sources [1].

Catalysts based on platinum have been pointed out as potential candidates for this process. Obuchi et al. (1993) demonstrated that at lower temperatures (typically below 300 °C) these metals could catalyze NO\textsubscript{x} reduction by the hydrocarbons found in the exhaust (e.g. propane and propylene) under lean-burn conditions [4]. It is found that Pt has the highest NO\textsubscript{x} reduction activity under lean conditions among the platinum group metals [5,6]. However, this high activity is accompanied by low N\textsubscript{2} selectivity, i.e. large quantities of N\textsubscript{2}O are formed over Pt under lean conditions [5]. And N\textsubscript{2}O is an important greenhouse gas and air pollutant, having much more impact per unit mass (global warming potential) than carbon dioxide according to the Environmental Protection Agency (EPA) [7].

Regarding the reaction mechanism, the technical literature proposes two main reaction pathways for low temperature selective catalytic reduction of NO on Pt catalysts. The first one involves production of molecular nitrogen through NO dissociative adsorption via a redox mechanism [8,9]. According to this scheme, NO is adsorbed on the Pt
surface and dissociates to yield adsorbed nitrogen and oxygen atoms, which desorb in the form of molecular N\(_2\) and/or N\(_2\)O, due to the reaction between two dissociated nitrogens and by one dissociated nitrogen and molecular NO, respectively. The role of the reductant is to react with adsorbed oxygen atoms and regenerate the active sites. The other mechanism proposes that the activation of the hydrocarbon plays the key role in the lean-DeNO\(_x\) reaction. In this sense, the activated hydrocarbon can react with adsorbed NO or NO\(_2\) \cite{10-12} to form organo-nitro species that later decomposes as N\(_2\) or N\(_2\)O. It has been also suggested that the adsorbed hydrocarbon can react with NO to form C\(_x\)H\(_y\)O\(_z\)N\(_w\) species \cite{13,14}, which would be later removed from the surface by reaction with oxygen, thus regenerating the active sites.

This research group has reported results on the preparation and characterization of silica sub-microtubes loaded with platinum nanoparticles, which showed a high activity and total selectivity to N\(_2\) at mild conditions, in the presence of excess oxygen, when using C\(_3\)H\(_6\) as reducing agent \cite{15}. Therefore, the aim of this work is to deepen into the behavior of this catalyst on this process, analyzing its performance under different experimental conditions to establish a possible mechanism for NO reduction by C\(_3\)H\(_6\) in the presence of O\(_2\). The experimental results have been correlated with a kinetic model that represents adequately these experimental data.

2. MATERIALS AND METHODS

2.1. Catalyst preparation

The silica sol was prepared from tetraethyl orthosilicate (TEOS), ethanol, distilled water, and HCl. The sol composition in molar ratio was 1:2:2:0.025 (TEOS:ethanol:water:HCl). Platinum (II) acetylacetonate was added to the solution in a
molar ratio to TEOS of 0.006. A more detailed explanation of the sol gel preparation can be found elsewhere [15].

Silica sub-microtubes were generated by using the coaxial electrospinning method reported in the literature [16] in a co-axial configuration, with the sol gel, which plays the role of carrier, coming through the external capillary tip and synthetic oil flowing through the inner one. The flow rates through the needles were around 0.6/1.5 mL·h⁻¹ for sol gel/synthetic oil, respectively. To apply the high voltage between the spinneret and the collector, two high voltage power supplies are used: one positively polarized connected to the needle and the other one negatively polarized attached to a collector. The tip-to-collector distance was 20–25 cm, and the electrical potential difference was 10 kV (the collector was at –5 kV and the tips at +5 kV).

The electrospun tubes with platinum, denoted as SiT-Pt, were easily collected as a flexible non-woven mat, and were calcined at 500ºC for 2 hours in order to stabilize them.

2.2. Catalyst characterization

A deep characterization was already performed and reported [15]. In this work, the surface chemistry of the samples before and after the reaction at different experimental conditions was studied by X-ray photoelectron spectroscopy (XPS) analysis, using a 5700C model Physical Electronics apparatus with MgKα radiation (1253.6 eV). For the analysis of the XPS peaks, the C1s peak position was set at 284.5 eV and used as reference to locate the other peaks. The fitting of the XPS peaks was done by least squares using Gaussian-Lorentzian peak shapes.

The surface and inner morphology of the tubes was studied by scanning electron microscopy (SEM) using a JSM 840 JEOL microscope working at 25 KV voltage and
by transmission electron microscopy (TEM) in a Philips CM200 microscope at an
accelerating voltage of 200 kV and in a high angle annular dark field (HAADF) FEI
Titan G2.

2.3 NO Selective Catalytic Reduction (SCR) experiments

The NO reduction experiments were performed in a quartz fixed bed microreactor (4
mm i.d.) at atmospheric pressure. Experiments were carried out with 80 mg of catalyst.
The total flow rate was varied from 100 to 250 cm$^3$ STP/min for different
concentrations of NO ranging from 200 to 800 ppm and C$_3$H$_6$ from 200 to 1500 ppm.
The concentrations of other inlet gases were 3% for O$_2$ and 200 ppm for N$_2$O. A
chemiluminiscent analyzer (EcoPhysics, CLD 700 AL model) was used to measure the
outlet gas concentrations of NO and NO$_2$. The CO and CO$_2$ outlet concentrations were
analyzed by means of a non-dispersive infra-red analyser (Ultramat 22, Siemens
model). C$_3$H$_6$, H$_2$O, N$_2$, N$_2$O and O$_2$ concentrations were measured by a mass
spectrometer analyzer (Balzers MsCube).

2.4. Kinetic analyses

The mathematical equations to describe the NO reduction rates in the presence of
propylene (as reducing agent) and oxygen are obtained by establishing the kinetic rate
equation and then solving the molar balance to the fixed-bed reactor. The following
assumptions were taken into account: homogeneous distribution of active sites on the
catalyst surface; axial dispersion was discarded by adequate fixed bed length and reactor
geometry (L/D>20); the reactor operated at steady-state conditions; diffusional
constraints and transport limitations were negligible; and changes in temperature and
pressure within the reactor were neglected.
Plug flow integral reactor can be used for the interpretation of the experimental data. To this purpose the reactor mass balance equations (1) and (2) were numerically and simultaneously integrated to calculate the exit conversion of the NO reduction and C₃H₆ oxidation reactions,

\[
\frac{dX_{NO}}{d\left(\frac{W}{F_{NO}}\right)} = r_{NO} \quad \therefore \quad \int_0^{X_{NO}} dX_{NO} = \int_0^{W/F_{NO}} r_{NO} d\left(\frac{W}{F_{NO}}\right)
\]

\[
\frac{dX_{C3H6}}{d\left(\frac{W}{F_{C3H6}}\right)} = r_{C3H6} \quad \therefore \quad \int_0^{X_{C3H6}} dX_{C3H6} = \int_0^{W/F_{C3H6}} r_{C3H6} d\left(\frac{W}{F_{C3H6}}\right)
\]

where \(r_{NO}\) and \(r_{C3H6}\) represent the reaction rates of nitric oxide reduction and propylene oxidation (mol·s\(^{-1}\)·g\(^{-1}\)), respectively; \(X_{NO}\) and \(X_{C3H6}\) are the total conversions of NO and propylene, and \((W/F_{NO})\) and \((W/F_{C3H6})\) are the nitric oxide and propylene space times, respectively. The reaction progress towards each product formation can be calculated in the same way if required.

The dependence with the temperature of the kinetic and thermodynamic parameters, involved in the proposed mechanisms, was considered to follow the Ahrrenius (3) or the Van’t Hoff law (4), respectively,

\[
k_i = k_{oi}\exp\left(\frac{-E_{ai}}{RT}\right)
\]

\[
K_i = K_{oi}\exp\left(\frac{-\Delta H_i}{RT}\right)
\]

where \(k_{oi}\) and \(K_{oi}\) are the pre-exponential factors, \(E_{ai}\) the activation energy of the reaction \((i)\) and \(\Delta H_i\) the enthalpy of the equilibrium \((i)\). The optimization of the Arrhenius and
Van’t Hoff parameters involved in these equations were performed by minimizing the objective function:

\[ O.F. = \sum_i (X_{i, \text{exp}} - X_{i, \text{cal}})^2 \]  \hspace{1cm} (5)

where \( X_{i, \text{exp}} \) represents the value of the experimental conversions of the reactives involved in the model proposed and \( X_{i, \text{cal}} \) the ones calculated by solving the differential rate equations system by a modified Runge-Kutta method with Matlab 2013b software. The minimization of the equation (5) was based on the Levenberg-Marquart algorithm. The optimized kinetic parameters are used to simulate the conversion profiles at different temperatures, initial gas pressures, NO and propylene space times and inlet compositions.

3. RESULTS AND DISCUSSION

Figures 1a and b present SEM and TEM micrographs of the catalyst, respectively. As can be seen, the catalyst used consists of submicrometric tubes, very uniform in size and shape. The submicrometric tubes present total BET surface area of 144 m\(^2\)/g and around 1% (wt) of Pt. Figure 1 c and d despite high-angle annular dark field scanning transmission electron microscopy (HAADF-STEM) image of the wall of the submicrotube. The micrographs show the presence of well-dispersed platinum nanoparticles of around 2 nm. Furthermore, the selected electron diffraction pattern of the Pt nanoparticles suggests the mainly presence of metallic platinum.
Figure 1. a) SEM image, bar length (1μm); b) TEM micrograph of the catalyst, bar length (100 nm); c) HAADF-STEM of the catalyst surface (Pt: red particles), bar length (50 nm); d) HAADF-STEM of submicrotubes (Pt: pink particles; Si: green particles), bar length (50 nm).

Figure 2 shows the evolution of outlet gas concentration as a function of the reaction time for an experiment where the inlet gases were added sequentially to the catalyst previously described. Initially, only NO diluted in He (200 ppm, W/F_NO = 2.88 g·s/µmol) was introduced in the reactor at 210 ºC. After around 60 min, O_2 (3% vol) was added to the inlet stream and, finally, at around 120 min of reaction time, C_3H_6 (1500 ppm) was also introduced. In the first step only a low adsorption of NO was observed and no reaction products were detected. With the addition of oxygen to the inlet stream, about 50% of NO is oxidized to NO_2, due to the well-known high activity of metallic platinum as oxidation catalyst. With the addition of C_3H_6, the presence of NO_2 in the outlet gases is practically negligible. In this sense, some authors suggested that propylene is strongly adsorbed on the catalyst surface, decreasing the surface coverage of oxygen. This fact reduces the probability of the NO and O adsorption at adjacent vacant sites, and so, the presence of propylene may be considered to inhibit the surface oxidation of NO to NO_2 [3,17-19]. In this step, the conversion of NO is slightly improved; however, the selectivity is total to N_2. No formation of N_2O was detected, at least, within our detection limits, suggesting that NO was quickly dissociated, and no molecular NO adsorption was taken place [17,18,20], avoiding the formation of N_2O that is one of the main drawbacks reported in the literature for platinum catalysts [11,21,22]. Regarding propylene, there is not an equimolar ratio between NO and propylene converted, because the reductant is also able to be directly oxidized by oxygen at this reaction temperature, producing equals amounts of CO_2 and H_2O.
Figure 2. Evolution of outlet gas concentration as a function of reaction time, with 200 ppmV NO, 3%v O₂ and 1500 ppmv C₃H₆, at 210 ºC, W/F_NO = 2.88 g·s/µmol.

The stability of the catalyst under different experimental conditions is another important aspect for catalytic applications. The good behavior observed for the catalyst under atmospheres containing SO₂ was already reported in a previous work [15]. Now, the activity of the catalyst was evaluated at different reaction temperatures and inlet concentrations, and no signals of deactivation were observed. As an example, Figure 3 represents the NO conversion as a function of the time on stream with 200 ppmv NO, 1500 ppmv C₃H₆ and 3% O₂, at 200 ºC, W/F_NO= 2.88 g·s/µmol. As can be seen, the catalyst showed the same activity along the experiment, with the same selectivity toward N₂ and the corresponding characterization analyses of the catalyst after 8 hours of reaction indicated no significant changes on its properties.
3.1. Influence of NO concentration on its reduction

The effect of NO concentration on the SCR with 1500 ppmv C$_3$H$_6$ and 3% O$_2$ was evaluated at different temperatures and at fixed W/F$_{NO}$= 1.92 g·s/µmol. Figure 4.a-b shows the corresponding NO and C$_3$H$_6$ conversions as a function of NO inlet concentration at different reaction temperatures, respectively. As can be seen, the NO conversion increases, at a fixed space velocity, as the NO inlet concentration does. The increase of the propylene conversion is not as high as the one observed with NO, at the same experimental conditions, due to the competitive adsorption between both reactants, being NO adsorption favored with respect to the propylene one. For conversions lower than 20%, a differential mode of operation can be assumed in this plug flow reactor. Furthermore, as the inlet conversion is zero, the following equation can be used to determine an apparent reaction order with respect to NO conversion:

$$F_{NO0} \cdot \frac{x_{NO}}{W} = r_{NO} = k_{ap} \cdot C_{NO}^n$$  (1)
Figure 4. a-b) NO and C$_3$H$_6$ conversion as a function of NO inlet concentration, respectively, with 1500ppmv C$_3$H$_6$ and 3% O$_2$, at different reaction temperatures, and at fixed W/F$_{NO}$= 1.92 g·s/μmol (symbols: experimental data; solid lines: predicted data); c) Natural logarithm of the NO reaction rate as a function of the logarithm of the NO inlet concentration.
approximately 0.5 with respect to NO concentration, at the different temperatures evaluated. This half-order dependence suggests that the dissociative adsorption of NO must be probably involved in the reaction mechanism with this catalyst, under these conditions (temperatures lower than the one needed to reach the maximum NO conversion), in agreement with the redox mechanism proposed by Burch et al. [5,8,9].

3.2. Influence of C$_3$H$_6$ concentration on NO reduction

The influence of C$_3$H$_6$ concentration on NO reduction was analyzed by varying C$_3$H$_6$ concentration from 200 to 1500 ppmv, with 200 ppmv NO and 3% O$_2$, at different reaction temperatures and at fixed W/F$_{NO} = 2.88$ g·s/μmol. NO conversions as a function of the reaction temperature at different C$_3$H$_6$ concentrations are shown in Figure 5.a. The results clearly indicated that NO reaction is favored at higher propylene concentrations. Denton et al. (2001) reported that NO reduction strongly depends upon the $\theta_{HC}/\theta_O$ ratio. For NO to be reduced, $\theta_{HC}$ must be high enough to protect the surface from oxidation by O$_2$ and to permit NO adsorption [23]. Besides, the presence of propylene may be considered to inhibit the surface oxidation of NO to NO$_2$ [3,17,18,19]. In this sense, NO conversion with 200 ppmv C$_3$H$_6$ at 220 ºC was 28.6%, being the selectivity to NO$_2$ approximately 12%. However, the NO conversion with 800 ppmv C$_3$H$_6$, at the same reaction temperature, was 64.2%, obtaining in this case, a selectivity value to NO$_2$ lower than 2%. The rest was converted to N$_2$. With 1500 ppmv C$_3$H$_6$, the selectivity to NO$_2$ was negligible. In contrast, all NO converted was selectively reduced to N$_2$. All these results suggest that NO to C$_3$H$_6$ molar ratios higher than one must be used to obtain a high and selective NO reduction to N$_2$. In agreement with these results, Denton et al. (2001) observed that N$_2$ selectivity is also strongly enhanced by the increase of C$_3$H$_6$ inlet concentration [23].
Figure 5. a) NO conversions as a function of the reaction temperature at different $C_3H_6$ concentrations, with 200 ppmv NO and 3% O$_2$, and at fixed $W/F_{NO} = 2.88 \text{ g·s/μmol}$. b) Natural logarithm of the NO reaction rate as a function of the logarithm of the $C_3H_6$ inlet concentration.

To evaluate the dependence of NO reduction rate on $C_3H_6$ concentration, the natural logarithm of the NO reaction rate as a function of the logarithm of the $C_3H_6$ inlet concentration at different reaction temperatures, was represented in Figure 5.b. Half-order dependence with respect to $C_3H_6$ inlet concentration was also observed, which can be associated to the activation of the reductant by dissociative adsorption. These results
are also in concordance with the formation of a carbonaceous intermediate on the active
Pt sites that can react with NO.

3.3. Influence of NO concentration on C₃H₆ oxidation

The range of application of this kind of catalyst strongly depends on its ability to
perform the activation (oxidation) of the reductant. Therefore, it is quite important to
analyze the behavior of the catalyst with respect to the reducing agent. For this goal, the
oxidation of propylene was tested with this catalyst at different propylene
concentrations in the presence and absence of NO. Figure 6.a collects the propylene
conversions as a function of the reaction temperature with different inlet concentrations,
but in these experiments W/F₇C₃H₆ was not constant. As can be seen, this catalyst is very
active for the propylene oxidation at the temperature range studied, obtaining a total
conversion of propylene at 200 ºC, with 200 ppmv C₃H₆, and 60% with 1500 ppmv
C₃H₆. The addition of only 200 ppmv NO shifted the oxidation curve to higher
temperatures; in this case, the temperature must be increased about 40 ºC to observe the
same propylene conversion. Some authors pointed out that C₃H₆, NO, and O₂ are
adsorbed on the same type of Pt adsorption sites [21]. So, it seems that this inhibition
may be directly related to active site occupation by atomic N produced by NO
dissociation and/or adsorbed nondissociated NO molecules. In this case, NO surface
coverage on the Pt surface must be higher than the one corresponding to O₂, thus
decreasing the probability of propylene combustion [3,22].
Figure 6. a) Propylene conversions as a function of reaction temperature at different inlet concentrations, with 200 ppmv NO and 3% O₂, and at fixed W/F₉NO = 2.88 g·s/μmol. b) Natural logarithm of the C₃H₆ reaction rate as a function of the logarithm of the NO inlet concentration, at fixed W/F₂C₃H₆ = 0.38 g·s/μmol.

To study how the NO concentration affects to the rate expression of propylene oxidation, C₃H₆ inlet concentration was fixed to 1500 ppmv and NO concentration was varied from 200 to 800 ppmv, with 3% O₂, at different reaction temperatures (W/F₉C₃H₆ = 0.38 g·s/μmol). Figure 6.b. shows the natural logarithm of the C₃H₆ reaction rate as a
function of the logarithm of the NO inlet concentration, at different reaction
temperatures. As can be observed, a negative half-order term with respect to NO was
obtained at these experimental conditions. These results also support the partial
inhibition of the propylene oxidation due to the possible presence of strongly (and
apparently dissociatively) adsorbed NO, in agreement with the results reported by
Nikolopoulos et al. [23].

3.4. Influence of N\textsubscript{2}O concentration on NO reduction

One of the main drawbacks reported in the literature for platinum catalysts is the
formation of N\textsubscript{2}O. Its formation during NOx SCR is mainly associated to the reaction
between adsorbed N (derived from the dissociative adsorption of NO) and NO
molecularly adsorbed [11,17,21,22]. However, some authors proposed that N\textsubscript{2}O is an
intermediate for N\textsubscript{2} formation [22].

A negligible outlet gas concentration of N\textsubscript{2}O was observed with this catalyst at the
experimental conditions studied, in agreement with the results observed by Yang and
Jung using H\textsubscript{2} as reducing agent. These authors found that only N\textsubscript{2}O was formed at low
temperatures, meanwhile the formation of N\textsubscript{2} was predominant at temperatures over 80
°C [24].

This finding can be associated to two different hypotheses: a) the dissociative
adsorption of NO is so fast, that the presence of NO molecularly adsorbed is negligible;
b) if N\textsubscript{2}O is an intermediate for N\textsubscript{2} formation, the transformation reaction of N\textsubscript{2}O to N\textsubscript{2}
must be very quick. To analyze the role of N\textsubscript{2}O, two different kinds of experiments
were carried out. Firstly, the reaction of N\textsubscript{2}O was evaluated at several conditions: with
only 200 ppmv N\textsubscript{2}O, with 200 ppmv N\textsubscript{2}O and 3% O\textsubscript{2} and with 200 ppmv N\textsubscript{2}O, 1500
ppmv C\textsubscript{3}H\textsubscript{6} and 3% O\textsubscript{2}; all of them at 200 ºC and a space velocity of 2.88 g·s/μmol. The
conversion of N\textsubscript{2}O was negligible at these conditions. In this sense, Konsolakis et al. (2012) observed that N\textsubscript{2}O reacted at temperatures higher than 300 °C \cite{25}.

On the other hand, an experiment with 200 ppmv NO, 200 ppmv N\textsubscript{2}O, 1500 ppmv C\textsubscript{3}H\textsubscript{6} and 3% O\textsubscript{2} was also performed. Figure 7 shows a comparison between the NO conversion as a function of the reaction temperature in the presence and absence of N\textsubscript{2}O. The profile was very similar in both cases, which seems to indicate that the formation of N\textsubscript{2} does not take place via N\textsubscript{2}O intermediate.

3.5. Role of O\textsubscript{2} on NO reduction

Figure 8 shows the evolution of outlet gas concentration as a function of the reaction time for an experiment where the inlet gases were added sequentially. Initially, only 3% O\textsubscript{2} was introduced in the reactor at 210 °C. After around 60 min, NO diluted in He (200 ppm, W/F\textsubscript{NO} = 2.88 g·s/µmol) was added to the inlet stream and, finally, at around 120
min of reaction time, C₃H₆ (1500 ppm) was also introduced. Some differences can be noticed by comparing the second step of this figure with the one shown in Figure 2, corresponding to the oxidation of NO. The NO conversion is the same in both cases (48%), but a prompt evolution of NO₂ can be observed in Figure 2. On the contrary, a certain induction time in the formation of NO₂ appears in Figure 8 and the time required to achieve a pseudo steady state in this last experiment is much longer than the one represented in Figure 2, where the steady state is immediately reached.

Figure 8. Evolution of outlet gas concentration as a function of reaction time, with 3%v O₂, 200 ppmv NO and 1500 ppmv C₃H₆, at 210 °C, W/F₁O = 2.88 g·s/µmol.

With the sequence NO-NO+O₂, the NO surface coverage must be quite high and the addition of oxygen produces the rapid reaction to NO₂. In contrast, the previous addition of O₂ seems to imply O₂ adsorption and when NO is added to the inlet stream, this must be then adsorbed, probably, displacing oxygen from the Pt active sites. The long time required to achieve a pseudo steady state in this case seems to indicate that a large NO surface coverage is required for its oxidation to take place and that the surface
population of O\textsubscript{2} must be significantly decreased. On the other hand, it is important to mention that once the steady state is reached, only 65\% of the NO converted evolved as NO\textsubscript{2} at the outlet stream, suggesting either the partial adsorption of NO or the formed NO\textsubscript{2}. In this sense, Khosravi et al. (2014) analyzed different kinetic models reported in the literature for the oxidation of NO, preferentially based on Eley-Rideal models, and even including the possible inhibition effect of the NO\textsubscript{2} adsorbed [26]. Similarly, Denton et al. also observed that NO\textsubscript{2} reacts with propylene to only NO nor N\textsubscript{2} or N\textsubscript{2}O [22]. Therefore, these results could indicate that the large initial evolution of NO (see Figure 8) when propylene was added is related to the reaction between adsorbed NO\textsubscript{2} and propylene. Then, when steady state is reached, the preferential formation of N\textsubscript{2} is detected.

In order to clarify if there is a competition between NO and O\textsubscript{2} with our catalyst for the active sites with a preferential adsorption of NO or if O\textsubscript{2} is completely displaced by NO at this temperature, different experiments were performed. Firstly, the catalyst was treated with a stream containing only NO (200 ppmv) at 200 \textdegree C, then a temperature programmed desorption (TPD) was carried out up to 500 \textdegree C. All NO adsorbed was desorbed at the same temperature (physisorption), without any evolution during TPD. The same experiment was carried out but using 3\% O\textsubscript{2}, at the same temperature, and, in the same way, the oxygen adsorbed was evolved during the desorption step, with a negligible evolution during the TPD. The adsorption of O\textsubscript{2} was also analyzed at 260 \textdegree C; the adsorbed amounts were quite similar at 200 and 260 \textdegree C, and in neither of both experiments the evolution of O\textsubscript{2} was detected during TPD.

The same experiment was carried out but only using 3\% O\textsubscript{2}, at 200 \textdegree C and 260 \textdegree C. The oxygen adsorbed was similar in both experiments and all of it evolved during the desorption step, with a negligible evolution during the TPD.
In another test, the NO adsorption was also evaluated at 200 °C, but in this case, the catalyst used was previously reacted with NO-O₂-C₃H₆ at 260 °C. The corresponding results are shown in Figure 9. As can be seen, an important and exponential O₂ evolution was observed during the treatment with NO, which takes place simultaneously to a decrease of the NO concentration. Furthermore, a low formation of NO₂ can be also noticed. The adsorption of oxygen seems to be very stable at the highest temperature range. During the desorption step, all NO adsorbed was completely desorbed. These results suggest that O₂ is greatly adsorbed on Pt surface in the absence of other gases in the inlet stream or at high temperatures (temperatures higher than the one at which the maximum NO conversion is obtained, Tmax). The addition of NO at low temperatures produces the displacement of oxygen from the Pt active sites.

Figure 9. Evolution of outlet gas concentration as a function of reaction time, with 200 ppmV NO, at 210 °C, after reacting with NO-O₂-C₃H₆ at 260 °C.

Finally, the catalyst was treated with 3% O₂ at 260 °C for 1 h and then the oxygen was desorbed at the same temperature. At this temperature, a stream containing 1500 ppmv C₃H₆ was fed for 1 h, and subsequently desorbed. Then, the catalyst was cooled to 200 °C and followed by a TPD up to 500 °C. The adsorption of O₂ was close to 6 mmol/g.
During the desorption step at 260 °C, the amount of O\textsubscript{2} desorbed (corresponding to physisorbed O\textsubscript{2}) was 5.66 mmol/g. So, 0.34 mmol/g of O\textsubscript{2} must remain strongly adsorbed on the catalyst surface. With the addition of propylene at 200 °C, a low formation of CO\textsubscript{2} can be observed (0.035 mmol/g). The evolution of oxygen was not observed, in this case. Therefore, it seems that the oxidation of propylene is favored, instead of the displacement of oxygen from the active sites, at this high temperature. During the cooling step, an additional CO\textsubscript{2} evolution was also detected (0.28 mmol/g), suggesting that all O\textsubscript{2} adsorbed was available for the reductant oxidation. In agreement with these results, Garcia Cortes et al. (2007) reported that the surface coverage of oxygen is very low and there exists a direct competition between NO and O\textsubscript{2} for Pt adsorption sites, being favorable to NO, at temperatures below Tmax. However, the catalyst surface is mainly covered by oxygen species at temperatures higher than Tmax [19]. In this line, Li et al. also found a competitive adsorption between NO and O\textsubscript{2} with a Pt/SAPO-34 catalyst, but using CO as reducing agent [27].

3.6. Reaction mechanism

3.6.1. NO oxidation

This reaction is exothermic and is limited by its equilibrium at high temperatures. There are many works in the literature which deals with the oxidation of NO on platinum catalyst. An Eley–Rideal-type mechanism involving dissociative adsorption of O\textsubscript{2} and reaction of NO from gas phase is mostly used to model the NO oxidation reaction on Pt catalysts [28-30]. However, the results obtained in the present work by adding the gases sequentially seem to indicate that a certain NO surface coverage is required for the oxidation reaction to take place. In this sense, some authors have found that a
The Langmuir-Hinshelwood model is more adequate to model the NO oxidation reaction [31,32]. Therefore, the following reactions are proposed to describe the NO oxidation:

\[
\begin{align*}
\text{Reaction 2:} & \quad \ast + NO \xleftrightarrow{K_{NO}} \ast NO \\
\text{Reaction 3:} & \quad \ast + O_2 \xleftrightarrow{K_{O2}} \ast O_2 \\
\text{Reaction 4:} & \quad \ast + \ast O_2 \xleftrightarrow{K_{O2d}} 2 \ast O \\
\text{Reaction 5:} & \quad \ast NO + \ast O \xrightarrow{k_{NO2}} \ast NO_2 + \ast \\
\text{Reaction 6:} & \quad \ast NO_2 \xleftrightarrow{K_{NO2}} NO_2 + \ast 
\end{align*}
\]

Reaction 2 makes reference to the equilibrium adsorption of NO. O\(_2\) adsorption is assumed to proceed through a molecular precursor (reaction 3), followed by the dissociation of the precursor to atomic oxygen (reaction 4), due to oxygen dissociation on Pt surface proceeds via a precursor-mediated reaction path [31]. Reaction 5 considers the surface reaction between NO adsorbed and dissociative oxygen adsorbed to form NO\(_2\). The equilibrium adsorption of the NO\(_2\) formed is represented in Reaction 6. This last reaction is supported by the work of Mulla et al. (2006). They included a certain inhibition effect in the kinetic model due to the adsorbed NO\(_2\), which partially inhibited the Pt active sites [32].

Some authors reported that adsorbed NO predominantly covers the catalyst surface at low temperatures (<150 ºC), which is due to its high sticking coefficient on Pt. As the temperature is increased, the surface becomes predominantly covered with O until, at a very high temperature (~400 ºC), adsorbed O starts desorbing as O\(_2\), which results in an increase in the vacant site coverage [31].
3.6.2. NO reduction with C\textsubscript{3}H\textsubscript{6}

As aforementioned, two main reaction mechanisms are reported in the literature to describe the NO reduction in the presence of propylene and oxygen. The first one involves production of molecular nitrogen through NO dissociative adsorption via a redox mechanism. The other mechanism proposes, in a simplified way, that the activated hydrocarbon react with NO or NO\textsubscript{2} to finally decomposes to N\textsubscript{2} or N\textsubscript{2}O.

Based on the results previously commented, the following reactions can be also considered in the mechanism for the low temperature SCR:

\begin{align*}
& \text{}^* + ^* \text{NO} \xrightleftharpoons[\text{K}_{\text{NO}_2}]{\text{K}_{\text{NO}_2}} ^* \text{N} + ^* \text{O} \quad (7) \\
& \text{}^* + \text{C}_3\text{H}_6 \xrightarrow[\text{K}_{\text{C}_3\text{H}_6}^{\text{O}}]{\text{K}_{\text{C}_3\text{H}_6}^{\text{O}}} ^* \text{C}_3\text{H}_6 \quad (8) \\
& \text{}^* \text{C}_3\text{H}_6 + ^* \text{O} \xrightarrow[\text{K}_{\text{C}_3\text{H}_6}^{\text{O}}]{\text{K}_{\text{C}_3\text{H}_6}^{\text{O}}} ^* \text{C}_3\text{H}_6 \text{O} + ^* \quad (9) \\
& \text{}^* \text{C}_3\text{H}_6 \text{O} + 4^* \text{O}_2 \xrightarrow[\text{K}_{\text{C}_3\text{H}_6}^{\text{O}_2}]{\text{K}_{\text{C}_3\text{H}_6}^{\text{O}_2}} 3^* \text{C}_2\text{O}_2 + 3^* \text{H}_2 \text{O} + ^* \quad (10) \\
& \text{}^* \text{N} + ^* \text{N} \xrightarrow[\text{K}_{\text{N}_2}^{\text{O}}]{\text{K}_{\text{N}_2}^{\text{O}}} ^* \text{N}_2 + 2^* \quad (11) \\
& \text{}^* \text{C}_3\text{H}_6 \text{O} + ^* \text{NO} \xrightarrow[\text{K}_{\text{C}_3\text{H}_6}^{\text{NO}_2}]{\text{K}_{\text{C}_3\text{H}_6}^{\text{NO}_2}} ^* \text{C}_3\text{H}_6 \text{NO}_2 + ^* \quad (12) \\
& \text{}^* \text{C}_3\text{H}_6 \text{NO}_2 + ^* \text{NO} + 3^* \text{O}_2 \xrightarrow[\text{K}_{\text{C}_3\text{H}_6}^{\text{NO}_2}]{\text{K}_{\text{C}_3\text{H}_6}^{\text{NO}_2}} ^* \text{N}_2 + 3^* \text{C}_2\text{O}_2 + 3^* \text{H}_2 \text{O} + 2^* \quad (13)
\end{align*}

The three reactants (C\textsubscript{3}H\textsubscript{6}, NO, and O\textsubscript{2}) are suggested to be adsorbed on the same type of Pt adsorption sites (denoted as *). However, in this case, the kinetic constants of reactions (3) and (4), corresponding to O\textsubscript{2} adsorption, must be significantly decreased at temperatures lower than Tmax, due to the surface coverage of oxygen is rather low at these temperatures. Reactions (5) and (6) are not going to be taken into account in the
kinetic model, due to the fact that the formation of NO\(_2\) in the presence of propylene is lower than 5% at best, and besides, its reduction produces the formation of NO nor N\(_2\) or N\(_2\)O [22].

A half-order dependence with respect to NO was observed for the NO reduction rate, what suggests that the dissociative adsorption of NO must be probably involved in the reaction mechanism, under the experimental conditions tested (temperatures lower than the one needed to reach the maximum NO conversion). This mechanism is represented by reactions (7) and (11). Nevertheless, the possibility of a mechanism based on the activation of the hydrocarbon cannot be completely ruled out. Therefore, it has also been considered in reactions (12) and (13), as pointed by Zheng et al. [33].

On the other hand, the absence of N\(_2\)O at the outlet stream can indicate the low presence of NO molecularly adsorbed on the catalyst surface. Furthermore, it is also observed that the formation of N\(_2\) does not take place via N\(_2\)O intermediate. So, the formation of N\(_2\)O has not been considered in this reaction mechanism.

With regard to the role of oxygen, Captain et al. (2000) also reported that molecular oxygen could be involved in the reaction pathway [11] and Nikolopoulos et al. (1990) found a first-order dependence of NO reduction and C\(_3\)H\(_6\) oxidation on O\(_2\) for Pt/alumina, suggesting the possibility of direct participation of O\(_2\) from the gas phase in the activation of the reductant or the removal of carbonaceous deposits [23]. In our case, the reduction of NO with propylene in the absence of oxygen was negligible, and only with the addition of oxygen was observed a significant NO conversion [15]. Besides, the results above described suggest that the surface coverage of oxygen at temperatures lower than Tmax is very low, so, the participation of oxygen from the gas phase in the
NO reduction has been considered in this reaction mechanism by reactions (10) and (13).

Finally, reaction (9) and (10) make reference to the own oxidation of propylene in the presence of oxygen. Although this oxidation is partially inhibited in the presence of NO, the amount of propylene oxidized is higher than the amount of NO reduced. Therefore, they must be included in the mechanism. Some authors even suggested that in the lower temperature region the activation of the hydrocarbon appears to be the kinetically significant step. Such a claim is supported by the observed delay in the hydrocarbon light-off in the presence of NO, the close proximity of the ascending part of the NO reduction curves and the corresponding hydrocarbon oxidation curves, and the coupling between the points of maximum NO conversion and complete hydrocarbon oxidation [8].

On the other hand, it is important to clarify that reaction (13) is not a direct reaction, but it involves the formation of different intermediates. However, no physical evidences of the possible intermediates are observed in these experiments, and the literature is not clear about this aspect. For this reason and for the sake of simplicity, this reaction has been considered by one unique step. However, a possible reaction pathway could be as follows:

\[ \text{C}_3\text{H}_6\text{NO}_2 + \text{NO} \rightarrow \text{C}_2\text{H}_6 + \text{N}_2 + \text{CO}_2 + \text{O} \quad (14) \]
\[ \text{C}_2\text{H}_6 + \text{O} \rightarrow \text{C}_2\text{H}_4 + \text{H}_2\text{O} \quad (15) \]
\[ \text{C}_2\text{H}_4 + \text{O}_2 \rightarrow \text{CH}_4 + \text{CO}_2 \quad (16) \]
\[ \text{CH}_4 + \text{O} \rightarrow \text{CH}_2 + \text{H}_2\text{O} \quad (17) \]
\[ \text{CH}_2 + \text{O} \rightarrow \text{CH}_2\text{O} \quad (18) \]

\[ \text{CH}_2\text{O} + \text{O}_2 \rightarrow \text{H}_2\text{O} + \text{CO}_2 \quad (19) \]

3.6.3. Rate equations and kinetic study

By considering, the adsorption equilibriums of NO, O\(_2\) and C\(_3\)H\(_6\) over the platinum site (reactions 3-5,8), and assuming that the surface coverage of dissociated oxygen and nitrogen are the same, it can be obtained:

\[ \theta_{\text{NO}} = K_{\text{NO}} \cdot C_{\text{NO}} \cdot \theta_f \quad (20) \]

\[ \theta_{\text{O}_2} = K_{\text{O}_2} \cdot C_{\text{O}_2} \cdot \theta_f^2 \quad (21) \]

\[ \theta_{\text{C}_3\text{H}_6} = K_{\text{C}_3\text{H}_6} \cdot C_{\text{C}_3\text{H}_6} \cdot \theta_f \quad (22) \]

\[ \theta_{\text{N}} = \theta_O = (K_{\text{NO}d} \cdot \theta_{\text{NO}} \cdot \theta_f)^{0.5} \quad (23) \]

Taking into account quasi steady-state for the formation rate of \(*\text{C}_3\text{H}_6\text{O}\) intermediate, and by considering reaction (13) much faster than reaction (12), the presence of \(*\text{C}_3\text{H}_6\text{NO}_2\) intermediate can be ruled out. So, the following expression can be drawn:

\[ \theta_{\text{C}_3\text{H}_6\text{O}} = \frac{k_{\text{C}_3\text{H}_6}\theta_{\text{C}_3\text{H}_6}\theta_{\text{O}}}{k_{\text{C}_3\text{H}_6}\theta_{\text{C}_3\text{H}_6} + k_{\text{O}_2} + k_{\text{C}_3\text{H}_6}\theta_{\text{NO}}} \quad (24) \]

Therefore, the site balance for the platinum active sites can be written as follows:

\[ 1 = \theta_f + \theta_{\text{NO}} + \theta_{\text{O}_2} + \theta_{\text{C}_3\text{H}_6} + \theta_{\text{N}} + \theta_{\text{O}} + \theta_{\text{C}_3\text{H}_6} \quad (25) \]

Finally, it is also considered that the NO reaction rate can be expressed as a combination of the contribution of the NO reduction by the redox mechanism, and by the activation of the hydrocarbon with the following reaction with NO adsorbed. Meanwhile, the
oxidation of propylene can be considered to take place directly by its reaction with
oxygen and also by its interaction with NO:

\[ r_{NO} = -k_{N2} \cdot \theta_{N^2} \cdot \theta_{C_3H_6O} \cdot \theta_{NO} \]  \hspace{1cm} (26)

\[ r_{N_2} = -\frac{1}{2} \cdot r_{NO} \]  \hspace{1cm} (27)

\[ r_{C_3H_6} = -k'_{C_3H_6} \cdot \theta_{C_3H_6O} \cdot \theta_{C_3H_6} \cdot \theta_{NO} \]  \hspace{1cm} (28)

The values obtained for the kinetics parameters and the kinetic constant values at 180
°C, for the NO reduction in the presence of propylene are shown in Table 1. The
parameters obtained by the resolution of the model equations indicate that the redox
mechanism, proposed by Burch et al. (5,8-9) presents a major relevance than the
mechanism of activation of the hydrocarbon, showing kinetic constant values at 180 °C
at least three orders of magnitude higher for the redox mechanism than those obtained
for the activation of the hydrocarbon. These results are in concordance with the high
selectivity to N₂, because the majority presence of dissociated NO avoids the formation
of N₂O by the reaction of molecular NO with N dissociated from NO.

Figure 4.a also represents as solid lines the estimated NO conversion as a function of
NO inlet concentration at different reaction temperatures and at a fixed space velocity of
W/F_NO = 1.92 g·s/μmol. Figure 10 shows the NO and C₃H₆ conversions, respectively, as
a function of the space-time at different reaction temperatures (NO inlet concentration =
400 ppm). The solid lines represent the NO and C₃H₆ conversions obtained from this
mechanism. The increase of the space time leads to higher conversion values. As can be
seen, both NO reduction and oxidation conversions are represented reasonably well by
the model proposed.
Figure 10. a) NO conversions as a function of the space time at different reaction temperatures, with 1500 ppmv C\textsubscript{3}H\textsubscript{6} and 3% O\textsubscript{2}, and at fixed NO concentration, 400 ppmv (symbols: experimental data; solid lines: predicted data); b) C\textsubscript{3}H\textsubscript{6} conversions as a function of the space time at different reaction temperatures, with 3% O\textsubscript{2}, and at fixed NO concentration, 400 ppmv (symbols: experimental data; solid lines: predicted data).

### CONCLUSIONS

The kinetic study for the NO reduction, in the presence of propylene as reductant agent, and in excess of oxygen, shows half-order dependence with respect to NO inlet concentration. These results suggest that the dissociative adsorption of NO must be probably involved in the reaction mechanism, under these experimental conditions (temperatures lower than the one needed to reach the maximum NO conversion).

On the other hand, the propylene oxidation reaction shows a negative half-order term with respect to NO, at these experimental conditions. These results also support the partial inhibition of the propylene oxidation due to the possible presence of strongly (and apparently dissociatively) adsorbed NO.

The influence of NO to propylene molar ratios has been also analyzed. High and selectively NO reduction to $N_2$ was observed, at NO to $C_3H_6$ molar ratios higher than one. Furthermore, the role of $N_2O$ on the NO reduction has been also evaluated. The results indicate that the formation of $N_2$ does not take place via $N_2O$ intermediate. With regard to the role of oxygen, it seems that the addition of NO at low temperatures produces the displacement of oxygen from the Pt active sites.

Based on all the experimental results, the proposed reaction mechanism considers that the three reactants ($C_3H_6$, NO, and $O_2$) are adsorbed on the same type of Pt adsorption.
sites and their corresponding fractional coverages will strongly depend on the experimental condition used. Besides, it takes into account that both the dissociative adsorption of NO and activation of the hydrocarbon can take place simultaneously. Furthermore, the participation of oxygen from the gas phase in the NO reduction has been also taken into account in this reaction mechanism. Lastly, the direct oxidation of propylene in the presence of oxygen and by its reaction with NO has also been considered.

The parameters obtained by the resolution of the model equations indicate that the redox mechanism (dissociative adsorption of NO) presents a major relevance than the mechanism of hydrocarbon activation followed by its reaction with NO. These results are in concordance with the high selectivity to \( \text{N}_2 \), because the majority presence of dissociated NO avoids the formation of \( \text{N}_2\text{O} \) by the reaction of molecular NO with N dissociated from NO. Both NO reduction and \( \text{C}_3\text{H}_6 \) oxidation conversions are represented reasonably well by the model proposed.
