Versatile barium and calcium imidazolium-dicarboxylate heterogeneous catalysts in quinoline synthesis

María Albert-Soriano,[a][‡] Paz Trillo,[a][b][‡] Tatiana Soler,[c] and Isidro M. Pastor*[a]

Abstract: This article details the development of heterogeneous catalysts based on calcium and barium in combination with the organic linker 1,3-bis(carboxymethyl)imidazolium (bcmim). The linker and the materials from alkaline earth metals are easily prepared under very smooth conditions. The use of linkers with different counterions (Cl or Br) provided different materials. Calcium and barium based catalysts were successfully employed in the preparation of quinoline derivatives from ketones and 2-aminoarylalddehydes or 2-aminoarylketones. Moreover, barium based catalysts provided better results than calcium, although the latter are an excellent complement for certain substrates. Thus, a notable feature of such catalysts is the possibility of accessing a variety of complementary heterogeneous catalytic systems, rendering the catalysis adaptive to the reactant.

Introduction

Quinoline moiety is present in several bioactive compounds, both natural occurring and synthetic. The spectrum of pharmacological applications covers different aspects, such as antifungal, antiviral, antibacterial, antimalarial, antplatelet aggregation and anti-inflammatory among others.[1] More recently, quinoline derivatives have shown anticancer activity by means of different mechanisms of action.[2] In this sense, the study of new approaches and/or protocols for the preparation of this type of heterocyclic derivatives is of relevant interest. One of the most employed routes in the preparation of quinoline derivatives is the Friedländer reaction,[3] Thus, the condensation between a carbonyl compound bearing hydrogens in the α-position and a 2-aminoketone or aldehyde allows the formation of the nitrogen-containing heterocycle in one synthetic step. The reaction can be either acid or base catalyzed.[4] Among the catalysts considered in this transformation, no alkaline earth metal based ones have been tested.[5] Regarding heterogeneous catalysts, alumina or acidic supported materials have been reported.[6] The use of metal-organic frameworks (MOF) as heterogeneous catalysts is nowadays of particular interest due to their specific characteristics.[7] Thus, the group of Cejka evidenced the idea that a metal-organic framework (MOF) can act as heterogeneous catalyst in the Friedländer reaction. Copper-MOF Basolite C-300 (HKUST-1) catalysed the coupling between pentane-2,4-dione and 2-aminobenzophenone or 2-aminoacetophenone.[8] Other copper based MOF, such as MOF-505 and MMCF-2, have been also proved to be active in the condensation between 2-aminobenzophenone and pentane-2,4-dione or ethyl 3-oxobutanoate.[9] The concept of MOFs acting as heterogeneous catalysts in this transformation has been just shown, albeit the catalyst has a lack of versatility in terms of reactants. Furthermore, the reuse of a heterogeneous catalyst is one of its important features, what can be a challenge in this type of transformation. Quinolines are nitrogen-containing compounds, which can be adsorptive removed from fuel and air by metal-organic frameworks.[9] Consequently, the product of the reaction may cause deactivation of the catalyst, reducing catalyst recyclability. Catalysis employing metal complexes is mainly based on transition metals, and the development of this area has been essential for synthetic organic chemistry. The use of alkaline earth metals, such as calcium and barium,[10] in catalytic systems has been surprisingly less studied, despite their economic and ecological benefits. There are few examples of the evidence of calcium or barium based hybrid materials[11] as heterogeneous catalysts, being just a simple test of the catalytic activity reported in each case. The group of Koner has described two barium-organic frameworks using pyridine-2,5-dicarboxylate[12] and 3,5-pyrazoldicarboxylate[13] as linkers, which have been employed as catalysts for the aldol condensation of various aromatic aldehydes with acetone and cyclohexanone with high yields and selectivities. Hybrid materials based on barium and 1,3,5-benzenetricarboxylate (BTC) have proved to be basic catalysts in Knoevenagel condensation and Michael addition reactions. The catalytic activity could be increased when they were pretreated at 320 °C to generate new active sites.[14] Barium linked with 5,5’-(2,3,6,7-tetramethoxyanthracene-9,10-diyldiisophthalate has been tested in the cyanosilylation of benzaldehydes and phenones and in the cycloaddition of carbon dioxide and epoxides.[15] The group of Monge and Gutierrez-Puebla has employed the linker anthraquinone-2,6-disulfonate with calcium and barium to generate heterogeneous catalysts for styrene hydrogenation and...
Results and Discussion

The organic linker 1,3-bis(carboxymethyl)imidazolium (bcmim) \(^{[22]}\) is easily prepared from readily accessible starting materials (i.e. formaldehyde, glyoxal and glycine), and it can be transformed into its corresponding halide salts by simple treatment with the corresponding hydrogen halide (Scheme 1). \(^{[23]}\) 1,3-Bis(carboxymethyl)imidazolium bromide (bcmim-HBr) in combination with basic calcium and barium salts gave the corresponding metal-organic frameworks bcmim-Ca1 and bcmim-Ba1 as colorless solids (Scheme 1 and Supporting Information), as previously reported.\(^{[24]}\) In an analogous way, the 1,3-bis(carboxymethyl)imidazolium chloride (bcmim-HCl) was treated with calcium carbonate and barium oxide, under very mild conditions, to form the materials bcmim-Ca2 and bcmim-Ba2, which were isolated also as colorless solids (Scheme 1 and Supporting Information). The obtained bcmim-Ca1, bcmim-Ca2, bcmim-Ba1 and bcmim-Ba2 were characterized by elemental analysis, inductively coupled plasma optical emission spectrometry (ICP-OES), powder X-ray diffraction (PXRD), thermogravimetric analysis (TGA), scanning electron microscopy (SEM) with energy dispersive X-ray (EDX) spectroscopy, and Fourier transform infrared (FTIR) spectroscopy (Supporting Information). It is worth noting the ease with which both the ligand (bcmim) and their metallic material derivatives are prepared.

At this point, we decided to test 2-aminobenzaldehydes, which have not been used in the Friedländer reaction catalyzed by
metal-organic frameworks as catalysts. For catalysts comparison, the coupling between 2-aminoo-3,5-dibromobenzaldehyde and pentane-2,4-dione was performed at 80 °C using microwave heating during 30 minutes (Table 1). The catalysts bcmim-Ca1, bcmim-Ba1 and bcmim-Cu provided the best results, giving the expected quinoline 1 with 34, 31 and 43% of conversion respectively (Table 1, entries 1, 3 and 5). We observed that the catalysts bcmim-Ca1, bcmim-Ba1 and bcmim-Cu were able to work for longer reaction times, and conversions of 59, 67 and 77% towards quinoline 1 were obtained after 90 minutes (Table 1, entries 6-8). The full conversion could be reached with catalyst bcmim-Ca1 when double amount of the diketone was used (Table 1, entry 9). In this case, product 1 was isolated pure with a yield >99% by simple filtration, which highlights the potential of this type of catalysts. On the contrary, we observed that the conversion obtained with catalyst bcmim-Ba1 remained roughly in the same level (65% conversion, Table 1, entry 10), and with bcmim-Cu was slightly increased giving 81% after the same reaction time (Table 1, entry 12).

Looking in more detail, an interaction could be observed between the amount of carbonyl compound and the catalysts employed. Indeed, there is a dependence of the conversion on the amount of diketone used (Figure 1), what can be explained by the slowing of the diffusion of the 2-aminobenzaldehyde towards the catalyst. However, the profile obtained for both catalysts is dissimilar, bcmim-Ca1 showing better performance than bcmim-Cu for higher amounts of diketone and vice versa (Figure 1). According to the graph depicted in Figure 1, a slight decrease in yield occurs when the number of equivalents of pentane-2,4-dione is superior to an optimum value. This effect could be observed also for catalyst bcmim-Ba1; the use of an excess of pentane-2,4-dione (20 equiv.) provided quinoline 1 with 61% yield.

Next, the reaction was performed employing other 2-aminobenzaldehydes, using catalyst bcmim-Ca1 under the best reaction conditions, i.e. microwave heating at 80 °C for 90 minutes in the presence of 10 equiv. of pentane-2,4-dione (Scheme 2). The reaction gave complete conversion when was carried out with 3,5-dibromo-2-aminobenzaldehyde or with 2,4-diamino-benzaldehyde, being possible to isolate the corresponding quinolines 1 and 4 with quantitative yields (Scheme 2). On the other hand, the rest of substrates tested gave the corresponding quinolines with low yield (Scheme 2, compounds 2, 3 and 5). The difference in reactivity cannot be attributed to electronic factors. Thus, best results were obtained with 2-aminobenzaldehydes having electron-withdrawing groups (i.e. bromo) and electron-donating groups (i.e. amino). Moreover, electron-withdrawing groups such as bromo and trifluoromethyl substituents provided very different reactivity. Consequently, the high reactivity of the 2-aminobenzaldehydes containing bromo and amino groups could be due to a possible helpful interaction between those functional groups and the heterogeneous catalyst aiding the approach of the substrate.

**Figure 1.** Correlation between the activity of the catalyst and the equivalents of pentane-2,4-dione. (●) for bcmim-Ca1 and (○) for bcmim-Cu. Reaction conditions: 2-aminocarboxylic aldehyde (0.2 mmol), pentane-2,4-dione (x equiv.), catalyst (10 mol-% metal based on ICP analysis), 80 °C, microwave heating (80 W), 90 min.

looking more in detail, an interaction could be observed between the amount of carbonyl compound and the catalysts employed. Indeed, there is a dependence of the conversion on the amount of diketone used (Figure 1), what can be explained by the slowing of the diffusion of the 2-aminobenzaldehyde towards the catalyst. However, the profile obtained for both catalysts is dissimilar, bcmim-Ca1 showing better performance than bcmim-Cu for higher amounts of diketone and vice versa (Figure 1). [a] Reaction conditions: 2-aminobenzaldehyde (0.3 mmol), pentane-2,4-dione (x equiv.), catalyst (10 mol-% metal based on ICP analysis), 80 °C, microwave heating (80 W), 90 min. [b] Conversion was obtained by GC analysis. In all cases, the selectivity of the reaction towards the formation of the quinoline product is >99%.

In order to continue our study, we considered the use of aminoaryl ketones as starting materials, which have been more generally used with other catalytic systems. The condensation of 2-aminobenzophenone with pentane-2,4-dione was chosen as the model reaction. Both reactants were heated in the presence of the corresponding heterogeneous catalyst at 80 °C using microwave heating (irradiation of 80 W, Table 3). All the catalysts provided conversion over 80%, although catalysts bcmim-Ca1 and bcmim-Ba1 performed slightly better than their analogous bcmim-Ca2 and bcmim-Ba2 and the corresponding copper catalyst. We also proved that the catalysts gave comparable levels of activity when the reaction is performed using conventional heating (80 °C, oil bath, Table 3), but the reaction times are longer.

The reaction mixture was separated from the solid catalyst by simple decantation using ethyl acetate. The catalyst could be reused in a new cycle after rinsing several times with diethyl ether and drying it. Following this simple work up the different catalysts were recycled, although their activity went down a tad in the following cycles (Table 3) with the exception of catalyst bcmim-Ba1. In fact, catalyst bcmim-Ba1 could be reused up to four times without appreciable loss of activity (Table 3, entry 3), both under conventional and microwave heating. Partial deactivation of these heterogeneous catalysts could be due to the presence of by-products remaining after the reaction. The standard washing (with EtOAc and EtOH) could be not enough in order to recover the original activity, being necessary another solvents and/or longer rinsing times. Consequently, the barium-organic framework bcmim-Ba1 resulted the most rugged heterogeneous catalyst among those considered in the present study. Moreover, the organic phases, after separation of the catalysts, were analysed by inductively coupled plasma-optical emission spectrometry (ICP-OES). The filtrates from the reaction with bcmim-Ba1 and bcmim-Ba2 had less than 0.01% of barium (refer to the catalyst loading), and the filtrates from the reaction with bcmim-Ca1 and bcmim-Ca2 had less than 0.44% and 0.17% of calcium respectively (refer to the catalyst loading).

Additionally, a reaction catalysed by bcmim-Ba1 was separated from the catalyst when the conversion was 24%, and the filtrate was allowed to react during 6 h, observing that the reaction stopped (27% conversion). This clearly proves that the reaction is heterogeneous catalysed by the MOF.

[a] Reaction conditions: 2-aminobenzophenone (0.3 mmol), pentane-2,4-dione (1.5 mmol), catalyst (10 mol-% metal based on ICP analysis). [b] Conversion was obtained by GC analysis. In all cases, the selectivity of the reaction towards the formation of the quinoline product is >99%. [c] Conversion of consecutive catalytic cycles (1st / 2nd / 3rd / 4th) with the same catalyst load.

For comparison, we considered the commercially available Cu-BTC MOF (HKUST-1, Basolite C-300), which has been reported previously in the coupling of 2-aminophenones and pentane-2,4-dione. The results, with HKUST-1 catalyst, reported in the literature are somewhat different depending on the reaction conditions. Therefore, we carried out the reaction with Cu-BTC MOF under the reaction conditions recorded in Table 3, using conventional heating, obtaining quinoline 6 with 77% conversion. Thus, the performance of HKUST-1 is in the mean-

imidazolium-dicarboxylate catalysts. Although, the catalytic activity of the calcium and barium catalysts is taking place in the external surface due to the low surface area and porosity of our catalytic systems.

To extend the versatility of this catalytic system we explored the use of other 2-aminophenones and carbonyl compounds (Scheme 3). In general, the reaction using microwave heating gave comparable to better conversions than the one using conventional heating, and in shorter reaction times. Appropriately, other β-dicarbonyl compound such as ethyl 3-oxobutanoate was coupled with 2-aminobenzophenone giving regioselectively the corresponding quinoline 7, which could be isolated with 80% yield. Cyclopentanone and different cyclohexanones reacted smoothly with 2-aminobenzophenone yielding the corresponding quinolines 10-14 (Scheme 3). The use of 2-aminobenzophenone in combination with pentane-2,4-dione or cyclohexanone provided the corresponding quinolines 9 and 16 respectively (Scheme 3), even though the conversion was lower than with 2-aminobenzophenone. This observation has been previously reported (with catalyst Cu-BTC MOF)\[7\] although the reaction was expected to work easily. Furthermore, substituted 2-aminobenzophenones were studied as reactants, providing quinolines 8, 15 and 17 (Scheme 3) with moderate to good conversions and yields. For the latter example, we proved that extending the reaction time the catalyst is still active, being possible to increase the yield. Indeed, the conversion was increased to 90% after 12 h of conventional heating, the product being isolated in 81% yield (Scheme 3).

As we have commented previously, we have at our disposal a variety of catalysts that allow us to try the improvement of the results. Therefore, 2-amino-5-chlorobenzophenone was reacted with pentane-2,4-dione, using microwave heating, in the presence of bcimim-Ca1 producing the quinoline 8 with a slight improvement (Scheme 4). Even more interesting resulted to prove that this calcium catalyst gave quinoline 9 with almost full conversion (Scheme 4). Nevertheless, this catalyst did not reach the full conversion in the preparation of quinoline 6 (Scheme 4). Consequently, the access to a 'toolbox' of readily available catalysts in order to open the range of substrates is an important characteristic of the work presented here.
This study also reveals the fact that small variations in the precursors of this type of heterogeneous catalysts can modify their activity as observed when comparing the activity of \textit{bcmim-Ca1} with \textit{bcmim-Ca2} or \textit{bcmim-Ba1} with \textit{bcmim-Ba2}. In our case, the only difference is the counterion of the organic linker used in the preparation of the material (i.e. chloride or bromide). Thus, we postulate that the halide influences the process of self-assembly that results in the formation of the final structure, packing in different manner. Indeed, their crystallinity differ as observed in the powder XRD analysis (see Supporting Information). Materials \textit{bcmim-Ca1} and \textit{bcmim-Ba1} have been previously characterized by X-ray diffraction by Dyson and co-workers.\textsuperscript{[24]} Furthermore, material \textit{bcmim-Ca2} has been characterized by X-ray diffraction analysis. In compound \textit{bcmim-Ca2}, there are water molecules per asymmetric unit. Each calcium is bound by six imidazolium anions via one of their carboxylate oxygen atoms (bonding distances in Figure 2). These imidazolium anions act as bridges that link Ca atoms in layers that extend perpendicular to the \textit{b} axis (Ca1-Ca1 distance along the \textit{a} axis: 4.8879(6) Å; Ca1-Ca1 distance along the \textit{c} axis: 7.1117(12) Å) (Figures 3 and 4). These layers are connected among them by hydrogen bonds with the water molecules present in the crystal. The main difference with \textit{bcmim-Ca1}\textsuperscript{[24]} is that halide (Cl) anion is not present in the crystal structure, due that the Ca coordination sphere is completed with imidazolium anions and crystal charge is compensated these way.

\end{itemize}
Conclusions

To conclude, this study has expanded the use of heterogeneous catalysts based on alkaline earth metals (such as calcium and barium). The preparation of a variety of heterogeneous catalysts based on calcium and barium was achieved by means of a straightforward and easy to carry out procedure. This study also showed that small variations in the metal-organic framework precursors, such as the counterion of the organic linker, provided different patterns in the final structure, what can influence in the catalytic activity of the heterogeneous catalyst.

The set of prepared catalysts is a toolkit to mediate in synthetic processes, such as the synthesis of quinoline via Friedländer reaction. The catalytic systems presented allow the reaction to occur between carbonyl compounds and not only 2-aminobenzophenones but also 2-aminobenzaldehydes, which have not previously been reacted in the presence of metal-organic frameworks for quinoline synthesis. Both, conventional heating or microwave heating can be employed with similar results in this transformation, although longer reaction times are needed for the former. Furthermore, the reusability of this type of catalysts have been proved, the material bcnim-Ba1 being the most robust among the considered in this study.

Experimental Section

General. All reagents and solvents were used as supplied commercially. Analytical thin-layer chromatography (TLC) was performed on 0.2 mm coated Science silica gel (EM 60-F254) plates purchased from Merck, Germany. Visualization was achieved by UV light (254 nm). Flash column chromatography was achieved using silica gel (hexane-ethyl acetate as eluent) or m (multiplet).

3.693(2)º, obtained from a Bruker Smart CCD diffractometer with graphite idealized positions and refined using a riding model. The positions of the atoms, except the water hydrogens, were located in the Fourier difference map and refined using a riding model. The positional parameters of the water hydrogens were constrained to an O–H distance of 0.85 Å and an isotropic displacement parameter of 1.5 times Ueq of the oxygen atom.
